and mix thoroughly, and leave them to cool. Form the mass into small balls, as it will not stick to the fingers, and use them when opportunity offers. Liquid grafting wax is a very useful application, and is, perhaps, the most convenient for the purpose of all the mastics used for covering wounds and grafting. It is of the consistency of varnish, and is applied very thinly with a brush. Care must be taken not to lay it on thickly, for the surface hardens so rapidly the alcohol is prevented from evaporating. Rosin, 1 lb.; beef tallow, 1 oz.; spirits of turpentine, one tablespoonful; alcohol (95 per cent.), 6 ozs. Melt the rosin over a slow fire; when melted take it off and add the beef tallow, stirring it constantly; let it cool down somewhat, mix the spirits of turpentine little by little with it, and at last the alcohol in the same way. Should the alcohol be added while the mass is too hot much will be lost by rapid evaporation; if, on the contrary, it is too cool, it will form a viscid lump, and must be slightly heated again. Stirring briskly is indispensable to mix the ingredients thoroughly. In well-corked bottles it keeps for years. If in course of time it becomes too thick, the addition of some alcohol will make it liquid again. For this purpose it must always be warmed. It is a good plan to put the bottle containing it in boiling or hot water to accomplish this. They are generally used in preference to clay in nurseries where grafting is extensively carried on, because more expeditious; but where only a few trees are grafted well-prepared clay answers every purpose.

Wood Ashes (Suffolk Boy, Quebec).—We have no analyses of the wood to which you refer. The injury caused by the excessive use of the ashes was due to caustic potash. As to the quantity to use beneficially for different crops no one can determine this so well as yourself. The same quantity that you used with benefit to Carrots will be equally serviceable for Potatoes and most other garden crops, including Vines and fruit trees. For dressing young seedlings the ashes should be mixed with sand or dry soil to the extent of one-half, more or less, as you may find satisfactory. You ask for information that can only be obtained by experiments, and in this country the materials are not present for determining the points in question.

Vine Roots Cankered (G. S.).—You ask simply, "What is wrong with the Vine roots, cause and cure?" The brevity of your letter indicates that you prefer a brief reply, and in the absence of data to guide us we can only say that there is probably some corroding substance in the border, and the remedy is fresh and suitable soil.

Peach Buds not Swelling (J. L., Sussex).—Nearly all the buds are dead but what has caused them to dry up no one can tell without knowing the treatment which the trees have received during the past season. We can only say the growths are extremely poor and immature, but this is scarcely sufficient to account for the withering of the buds. Drought at the roots, a bad attack of red spider on the foliage, or dressing the stems with a strong insecticide, are calculated to have a disastrous effect on the buds. Whether we have indicated the cause in your case we have no means of knowing, but if the shoots sent are fair examples of the trees we have no hesitation in saying they have been either neglected or mismanaged in some way or other. The temperature has been too high, but that is not the cause of the evil in question.

Potting Azaleas and Camellias (M. R.).—You will find the information you require on potting Azaleas on page 176 last week. Pay particular attention to the instructions there given to pot firmly, and to the condition of the roots as to moisture at the time of potting. Repotting these plants when the soil in the pots is either very dry or very wet, or of saturating the fresh compost immediately after it is used, is fatal to success. See also our reply to "J. M." on page 178. The particular compost for and time for repotting Camellias depends very much on the condition of the plants. On this subject we cite from an article published in the Journal last year:—Potting is best done in early spring just as the plants are commencing growth, or trying to do so, by those who have a stove or other structure where the temperature ranges from 55° to 85°, and where syringing can be done freely and a moist atmosphere maintained. Those who have not such convenience, but possess a vinery in which the Vines start in a natural manner, may repot their Camellias when the Vine leaves fairly cover the roof, as the temperature suitable for Vines at that stage and onwards will be also suitable for the plants under notice. If the pots can be placed on a bed of leaves or other moist base it will be decidedly advantageous to the plants. With only a greenhouse at disposal the repotting should be deferred until the night temperature is 60° or thereabouts, and the plants should be grouped where they can be kept as close as possible, also shaded. This with light syringings will lessen the necessity for frequently watering the soil, and healthy root-action will be the sooner reduced. A good guide for repotting Camellias when there was not the requisite convenience for dealing with them before, is when the young growths cease to extend, and just as the last-formed leaves are attaining their full size; but the longer the potting is deferred the greater must be the care in preserving the healthy roots and preventing them drying; also the greater is the necessity for heat, shade, and moisture for effecting the recovery of the plants. As to soil, take half rather light but decidedly turfy loam containing no lime, the remaining half to consist of very fibrous Heath or Azalea peat—not bog—and leaf soil from leaves that have not fermented; mark the condition. To this add crushed charcoal and silver sand liberally, say together, so as to form an eighth part of the bulk. Mix the whole thoroughly. If this compost will not incite the production of roots nothing will.

Bulbs after Flowering (Idem).—Cut off the spikes as soon as the flowers fade to prevent the formation of seed. Place the plants in the lightest position at command, such as on a shelf in a greenhouse or in a frame from which frost is excluded, and water them as carefully as before flowering, giving a little weak liquid manure occasionally. The stronger and healthier the foliage is under the influence of sun and air, and the longer it is maintained in a fresh state, the better will be the condition of the bulbs for flowering next year.

Self-Improvement (E. A. B.).—Nothing could be more commendable than the manner in which you are employing your leisure hours; but we would counsel you not to attach too much importance to "taking lessons," nor to measure their value by the money expended alone. The lessons in question you must only regard as the beginning of your educational career.

In this respect they may be most useful, as they either will or ought to afford you a sound basis for subsequent acquirements. A thorough knowledge of the subjects named in your letter can only be had by a long course of study and persevering application, and it will depend entirely on your aptitude in turning your knowledge to account as to whether it will be of substantial service to you. We are glad to observe a decided improvement in your caligraphy, a neat clear style of penmanship being always desirable, and often of very great advantage to a gardener. You will do well, however, to guard against an extremely florid method, which, indulged in, will be considered pedantic. A correct and concise manner of expression must not be overlooked. This is of greater moment than good penmanship, and we point it out to you because your letter contains two errors in grammar and the repetition of a sentence that mars the composition. Shorthand may be useful to you or not, just as it is practised diligently. So far from your being made "perfect in six months," you will never be perfect unless you continually practise the art. Even the most expert shorthand writers find constant practice necessary for maintaining their proficiency. A knowledge of book-keeping is essential, also of geometry, and to a certain extent mathematics, while of chemistry as applied to agriculture and horticulture you are not likely to learn too much, nor of botany. But you may easily attempt too much at once and err by relying too much on others. Proficiency in grammar and composition will be of greater service to you than shorthand, but if you can become competent in all so much the better. It is not possible for us to estimate the money value of any lessons you may receive, as these necessarily vary. We note with approval the efforts you are making to attain knowledge, and you have our best wishes for your success. Either you are fanciful or we are, but we do not admire the use of blue ink on tinted paper of such a flimsy texture as you use, as letters thus written are the reverse of easy reading, and are not likely to be particularly acceptable to ladies and gentlemen to whom you may have to write in the transaction of business.

Names of Fruits (C. Holtby).—The Pear is Beurré Rance. The Apple is not known. (H. W.).—The Apple is the Pig's-nose Pippin. The shrub is Veronica elliptica, a spray of which was figured on page 145.

Names of Plants (Reader).—1, Pteris longifolia; 2, Phlebodium aureum. (C. O.).—Ruscus hypophyllum. (G. Cummins.).—Erica vernix coccinea.

COVENT GARDEN MARKET.—MARCH 5TH.

OUR Apple market is very dull, large quantities of common stuff being on hand. Hothouse Grapes are shy; prices rapidly going up. Vegetables without alteration. Market generally quieter.

GRASS SEEDS FOR LAYING DOWN LAND TO PERMANENT PASTURE.

(Continued from page 180.)

THE seeds best suited for mixed soils must now be referred to, for in some counties and districts they vary much, not only on one farm but also in a single field. We have cultivated a farm for many years whereon no single field possessed an even soil, and this is the case more particularly in those districts where the land is not level, for let the undulations be great or little the soil is sure to vary. It often occurs on chalk subsoils

as well as others, but in laying down mixed soils we must admit that in all our mixtures some of the seeds are not such as are best adapted for mixed or irregular soils. We therefore propose to treat this particular requisite in seeding in connection with the seeding of land intended for parks, which will always be required to be somewhat ornamental. The question of evenness of turf for ornamental purposes, nevertheless, must be connected with the feeding value of the turf after having obtained it as a permanent pasture. Since the revolution which has occurred in seeding down land for permanent pasture we have adopted a plan whereby we have a right, if our endeavours in the selection of seeds has been judicious, to expect nearly all prizes without any blanks. We have omitted to use the Rye Grasses from seeds adapted for permanent turf, and when necessity demands it we must omit also those like Cock's-foot, which are frequently called the coarser Grasses, however valuable they may be considered in the mixtures for various soils for which we have previously formed lists of seeds, to be sown upon certain soils of various shades and quality where the question of ornament was not necessary or advantageous. We shall probably find that chalk, sand, or gravel, as well as limestone soils where lying level, are frequently even in soil on the surface, however they may differ in the subsoil. If, therefore, we have a level and tolerably even soil we may venture to exclude Cock's-foot Grass entirely from our mixture of seeds, and use quantities of each as follows. Mixture of Grass and Clover seeds for park pastures and dry mixed soils generally:—

	lbs.
Cynosurus cristatus (Crested Dog's-tail)	5
Festuca duriuscula (Hard Fescue)	3
Alopecurus pratensis (Meadow Foxtail)	4
Anthoxanthum odoratum (Sweet-scented Vernal Grass) ..	4
Poa pratensis (Smooth-stalked Meadow Grass)	5
Festuca ovina (Sheep's Fescue)	3
Festuca pratensis (Meadow Fescue)	5
Achillea millefolium (Yarrow)	3
Trifolium repens (White Dutch Clover)	5
Trifolium minus (Suckling Clover)	3

Total quantity per acre..... 40 lbs.

It will be noticed that we have not only omitted the Cock's-foot Grass on account of its coarseness or tufty habit of growth, but also the Creeping Fiorin. Although it is a close-growing and productive Grass, it is not well adapted for the mixed soils for reasons previously assigned as objectionable.

A different part of our subject is now reached—viz., the seeding of moist or wet low-lying soils in the valleys or near to rivers or brooks, for whether such land is intended for irrigated meadows or otherwise, in pasture the mixtures we shall recommend for seeding will answer well in either case. In the vales we frequently find considerable tracts of peaty soils, and however infertile they appear and may be in their undrained condition, yet when laid out properly and formed to shed the water on the surface, trenched, and channelled for irrigation, the soil will become fertile in proportion as the seeds sown are suitable, and the depth of accumulated deposits of earthy materials is sufficient to compress the subsoil and render it firm on the surface. Very much in the same way without irrigation the ordinary low-lying land in large districts in the vales is little more than a peat bog. When, however, it has been tile-drained and a large addition of soil added to the surface and seeded with proper Grass, valuable permanent pastures have been secured, yielding abundant crops of Grass.

Peat soil is a deposit or accumulation of vegetable matters, which when full of water in the unimproved condition is completely inert and valueless, but when dry and weighted on the surface with various earthy materials becomes abundantly productive. We know that old pastures are valuable in proportion to the accumulation of humus formed by the annual decay of roots and leaves of the Grasses, which as Darwin assures us, has been converted by the action of worms into manure well adapted for the various Grasses. We have known just the same advantages accrue where mud-land has been reclaimed from the sea, for after the sea has ceased to flow over the surface, and the mud trenched and channelled and covered with a good coating of gravel, and the land has been seeded with proper Grass seeds, we have very productive pastures now where mud only prevailed before and the sea flowed over at every tide.

The following is a list of Grasses best adapted for these soils and circumstances connected with them as before noticed. The seeds which we recommend for forming low-lying meadows and irrigated meadows, as well as land reclaimed from peat bogs and

mudlands from the seashore, and converting them into permanent pasture, are as follows:—

	lbs.
Dactylis glomerata (Rough Cock's-foot)	8
Poa nemoralis (Wood Meadow Grass)	5
Poa trivialis (Rough-stalked Meadow Grass)	4
Festuca pratensis (Meadow Fescue).....	5
Phleum pratense (Meadow Cat's-tail or Timothy Grass)	3
Poa aquatica (Water Meadow Grass)	3
Alopecurus pratensis (Meadow Foxtail)	4
Avena flavescens (Yellow Oat Grass).....	4
Trifolium pratense perenne (Cow Grass or Perennial Clover)	4
Quantity per acre.....	40 lbs.

In each kind of Grass here named, although some have not been included in any former list under other circumstances, yet they will be found exceedingly productive when grown upon the above-named soils and under the special circumstances as previously related. We must also give our reason for omitting some of the Clovers except Cow Grass in the above list. It is, however, well known that for the irrigated meadows they are of little use generally, for the strong and excessive produce of the other Grasses named frequently overwhelms them, and they die out in consequence. This, however, although it may be much the same in low-lying and wet peaty meadows, yet on the higher portions of such meadows, the subsoil being sound and firm, the Water Meadow Grass (Poa aquatica) may be omitted, and the same quantity of white Dutch Clover may be introduced instead; otherwise we consider generally the list recommended contains every suitable Grass for the purpose.

As we have in our prefatory remarks mentioned ensilage, we may here state the Grass produced upon any soil and under any of the attendant circumstances above alluded to will be exceedingly well adapted for being preserved in a properly constructed silo. We must, however, defer any further observations relating to ensilage, as we shall have to make special reference to it in this Journal. Under the projects for irrigation we must also refer to land which is often found on either side of vale meadows, and frequently laid out as what we call catch meadows, the water being led on to the higher portion of the field; and then in the act of irrigation the water, in the endeavour to find its level in the lower portions of the meadow, is cut off by the cross trenches cut for catching the water by channels laid out for the purpose of respreading it, to be caught again in the same way and redistributed throughout the whole field. We have seen this done in numerous instances on the lower valleys near to brooks or rivulets, and at the same time have noticed much land, although under cultivation, similarly situated and well adapted for catch meadows. In such cases we wish to say that the alteration and the admixture of Clover seed instead of one or two of the Grasses which we named above, will apply with full force in seeding for catch meadows.

WORK ON THE HOME FARM.

Horse Labour.—This has been various, for although there has been a few fine drying days, yet it has not continued long enough to allow the work to be done in connection with preparing the land for Peas, Beans, summer Vetches, and early Potatoes, except upon some of the sharp sandy or gravelly soils. When the first settled dry weather occurs the Barley should be drilled, and next the Oats or drege, the latter being required chiefly for consumption of horses and cattle on the farm. The white Oats for sale of the early varieties, such as Canadian and Victoria White, need not be sown before the 14th of March until the 20th, and will then come to the harvest ten days before the Wheat. With reference to the Barley-seeding and drilling we advise that the Barley be drilled at 12 inches apart between the rows, for in our experience we have known the Barley when drilled at that distance has proved a good malting sample, while that put in at the usual distance of 7 inches between the rows has only yielded thin grinding Barley. This circumstance goes far to explain the fact that in samples of drege, in which case three bushels of Oats and one bushel of Barley per acre is usually sown, it is because the Barley has more room to mature when in admixture with Oats. We have not seen an instance of a thin sample of Barley when separated from the Oats; but we know farmers who make a rule, and corn-dealers also, to separate the samples of drege and sell the Barley for malting purposes, and it invariably pays them well for doing. In drilling early Peas for a double purpose—that is, picking in a green state or seeding, for this is done often when convenient to purchasers to buy and pick them in the green state, they should then be drilled at 20 inches at least between the lines. This gives not only room for cultivating with the horse and hand hoes, but affords room for picking green for market. If the land after the main rtion is picked should be clean, the land may then be ploughed a

good depth, burying not only the haulm of the Peas, but the weeds also before they can ripen their seed. In this way the land is well manured by the haulm and weeds and rendered capable of producing a full crop of Turnips sown. Rape early enough to be fed-off by sheep before the seeding for Wheat, or otherwise the Turnips may be ploughed-in, which will insure a full crop and prospect for Wheat. As soon as the spring seedings are done, or simultaneously with them, the land should be preparing for Mangold, Carrot, and Swede seeding.

The land for Potatoes should be planted the first dry weather, and if it was clean or cleaned in the autumn it will now require to be worked down with about two times with the heavy iron drags, and then proceed to plough and plant as fast as, or, in fact, during the ploughing to plant the sets in every third furrow by women by hand labour. We never advise dressing the land for Potatoes with yard or town dung, because whilst the work of carting out and spreading dung is going forward the season is often lost if wet weather occurs, whereas by manuring with guano and bone superphosphate mixed and cast into the furrow with the sets the work is completed and the seed time saved. We advise for use 4 cwt. of the best guano with 3 cwt. of bone superphosphate, mixed with about 10 bushels of damp ashes per acre, which, when strewed in the furrow with the sets, is equal to any amount of the best box dung that can be made, in the result of a Potato crop, and the seed time assured as much as can be done in our fickle climate. As a farm produce we prefer the Magnum Bonum Potatoes, and in friable loamy soil the Wheat is sure to produce well when sown after the Potatoes. We have known this succeed alternately on one field for a period of thirteen years, except that a crop of stubble Turnips in favourable seasons has been taken and fed off by sheep between the Wheat and Potatoes; but when the Turnips are ploughed in it goes a long way to manure for and insure a full growth of Potatoes.

Live Stock.—The Down ewes and their lambs, as well as some of the long-wooled kinds, are now arrived at an interesting period of their lives. The lambs, especially where they are healthy, and when they are intended to be fattened for the butcher as sucking lambs, will now require good shepherding and constant attention; and on some of the grass districts the stock will require—that is, the ewes—but little besides the grass if the season continues as mild as at present while we write, Feb. 25th, except the ewes are intended to be sold fat with the lambs side by side. In this case the ewes may have beanmeal mixed with damp chaff to prevent waste; the lambs, too, may be allowed with benefit a little of the best chaff of Clover or Sainfoin hay, together with cake and cracked peas, in troughs in a fold somewhere in the pasture of a few hurdles square, with lamb gates for them to feed separately from the ewes. In this case, if a few Carrots or Mangold can be cut and the cake and peas both in meal mixed with them, so much the better. The Down flocks on the hill farms as breeding-stock flocks will now be on the Swedish Turnips, in which case the lambs will be fed in advance of the ewes with cut roots mixed with cake and beanmeal, with good Sainfoin hay in the cages or racks, the ewes cutting their own food on the land, and getting a liberal allowance of good Clover or Sainfoin hay in the cages twice a day. The lambs, however, running in advance of the ewes eating Swede greens and Rape where every tenth drill has been grown purposely for them, with the best and choicest hay on the firm in the cages; farther on in the season they may get cut roots with advantage with cake and meal extra.

OUR LETTER BOX.

Rye Grass (IV. L.).—There are several kinds of this much used on hill farms in admixture with white or yellow Clover, especially where intended for sheep-feeding only, and when required to hold over the seeds for feeding the second year the perennial Rye Grass is generally selected for the purpose, and affords abundance of pasturage. The ordinary sorts of Rye Grass, however, attract but little attention now, and not as they did formerly before the Italian Rye Grass came into use.

REMARKS.

24th.—Fair, but only bright occasionally.
25th.—Cooler, and very changeable, bright sun and short sharp showers.
26th.—White frost early; fine day.
27th.—Foggy early, then fair, but cold.
28th.—Dull and cold, a few flakes of snow.
29th.—Generally fine.
1st.—The coldest day this winter, but bright and sunny.
A considerable fall of temperature has occurred, but not nearly so marked as one as that at the beginning of March, 1883.—G. J. SYMONS.

PRUNING ROSES.

NOTWITHSTANDING all that has been written on the danger of early pruning, a great number of persons can with difficulty refrain from applying the knife or secateurs to their rapidly growing plants. They are alarmed lest their Roses should be exhausted by the removal of such masses of green shoots and foliage as late pruning involves in such an early season as we are now experiencing. This is an important matter, and appears deserving of fuller consideration and examination than it has received at the present time.

"D., Deal," has more than once adduced examples of Roses not being weakened by the removal of long shoots studded with fresh growths and expanded foliage, and has shown that plants thus treated have afterwards grown in the most satisfactory manner and developed magnificent blooms in time for exhibiting. A week ago, in the small rosery of Mr. Crowley at Waddon House, Croydon, where the beds are in a very sheltered position, the plants were a thicket of green growths, not a few of the shoots being 4 or 5 inches long, and in some the buds could be felt in the tips. To cut off such a mass of vegetation timid persons would regard as a cruel process, on the ground that it must seriously weaken the plants. It may exhaust the soil, no doubt, to some extent; but, granting that there is sufficient food left in it, are the Roses really weakened at all? The excellent gardener at Waddon has passed the epoch of timidity in the history of Rose-pruning, and now looks on the plants and their future blooming with equanimity. I passed the same epoch ten years ago. The Roses at Waddon were similarly forward when pruned at the end of March last year, and if they were weakened thereby how are we to account for the luxuriant growths that followed, and which now, in turn, await the severe shortening that they will soon have to endure? The result will be the same as last year—free and strong growths and handsome blooms in June, unless some extraordinary late frost should occur to injure the shoots. It is to avoid such possible injury that the pruning of Roses is deterred, and the growth of the bloom-producing shoots retarded. The earlier pruning is done the earlier are the growths that must be relied on for flowering, and consequently the greater is their danger of being destroyed or seriously damaged. The later the pruning is done in reason, say in March, the greater is the liability of the plants to escape the danger indicated; in fact, the longer the buds at the base of the shoots can be kept dormant, yet remain bold and healthy, the safer will the aftergrowths be, and the greater the certainty of free unchecked growth during May and June.

But to the question of weakening. Experience suggests to me that Roses are not weakened by the removal of the growths under notice. It is to be remembered that a plant consists of roots as well as of stems and foliage. Strong branches indicate a vigorous tree, but it can only be made so by the free action of vigorous roots in fertile soil. If the strength of the roots is greater than that of the branches

the force of the sap will be so great that robust growth must follow; while if the balance is on the other side, the roots being the weaker part, the growth of the tree will be restricted. This is very apparent in the growth of Roses. If not pruned at all the growth will soon cease to be strong, and the blooms of necessity will be correspondingly small; but prune severely to bold buds on healthy growth, and the root-power will be concentrated on the few buds retained, and the resulting growths must be correspondingly vigorous, always assuming the soil is fertile.

Admitting the fact, for fact it is, that the greater the preponderance of root power over the strength of the branches the stronger the growth must be, we must also, I think, admit another thing, that the root-action of a Rose is very much greater at the middle of March, or after the branches bristle with healthy growths, than was the case a month or more earlier, or before the buds had started, or, at any rate, before any leaves had commenced unfolding. The growths now produced, and which, it is feared, must weaken the plants, have, more probably, a contrary effect, inasmuch as they have undoubtedly increased the roots, and these working in good soil must inevitably exert such force on the few buds to which the branches are reduced, that the resulting growth must be both quicker and stronger than if the root power were weaker. But does not the removal of such a mass of growths check the roots that have been summoned into activity? It may do so to a slight extent, but experiments conducted with Roses in pots for testing that point have not shown that the roots really suffer; they only rest for a few days, then go on as if refreshed by their temporary inactivity.

Whatever loss there is by deferring the pruning of Roses until after they have commenced growing freely, is the loss of a certain amount of nutriment from the soil; but if this loss is a gain to the Roses, and the saving of the food in the soil a loss to them (by their being cut by frost and unable to appropriate it), then the advantages appear to rest on the side of late pruning, regardless of the extent of the growth of the plants.

On page 186 last week, "A. M. B." wrote in favour of early pruning, and adduced as an instance of its safety successful results notwithstanding the severity of the weather immediately after the plants were pruned. Fortunately the inclement weather followed the pruning so quickly that there was not time for any growth to be made; but supposing the frost had occurred a fortnight or three weeks later, as it is quite as likely to do as not in March, the young growths must have been damaged. Under the circumstances the Roses in question appear to have had a lucky escape.

The chief object of these notes, however, is not to insist on any particular date as the best for pruning Roses—as this can only be rightly determined by individual cultivators who know the local climatic peculiarities which cannot be safely ignored—but as an endeavour to dissipate the fears of those individuals who are anxious to delay the pruning as long as possible, in the hope that the growths on which they must rely for the coveted blooms will escape the frosts of April and early May that are often so disastrous, but who yet are haunted with an uncomfortable feeling that their plants are being exhausted by the growth that is now so prominent, and which every day increases to an apparently dangerous extent. They would be exhausted, no doubt, if the growths were allowed to extend indefinitely—that is, if the Roses were not pruned at all; but pruned in the ordinary manner a strengthening rather than a weakening of the plants occurs. The long shoots that are removed amount very much to a question of removing ninety out of a hundred sheep from a pasture, leaving all the more food for the ten remaining, which have the correspondingly better chance to "eat and get fat," and proverbially farmers like fat sheep, and rosarians fat blooms.

All the food taken out of the soil by the removal of the

growths with which unpruned Roses are now furnished can be restored by one copious application of liquid manure, and this should be given when the pruned plants have fairly started into growth.

When dwarf Roses are grown in beds, and a profusion of flowers of good quality is coveted rather than a limited number of exceptional merit for exhibition, then a number of the strong growths can be pegged down with advantage instead of shortening them in the orthodox manner.—EXPERIENTIA DOCEAT.

SPRING TREATMENT OF ASPARAGUS.

If well attended to in spring this favourite and valuable vegetable will require little attention throughout the season. It is a great advantage for cultivators to raise their own young stock, as Asparagus roots suffer much through being taken up, sent a long distance, and kept out of the soil for a considerable time. Many roots will die from this treatment, and more still will receive a check from which they will not readily recover. When everyone raises his own plants this difficulty has not to be contended with, as the ground may be ready for the plants before they are taken up, and then they need not be out of the soil or exposed to the air for more than a few minutes. In this way they will experience no check from being transplanted, and the advantage of one or two years' growth will be gained. Two or three hundred plants may be raised in a bed 4 feet wide and 10 or 12 yards long. Early in April is a most suitable time to sow the seed, and it may be dealt with like Onions or any other ordinary crop.

Transplanting the young roots into their permanent quarters is an operation of the greatest importance, as on this depends their ultimate success. Soil for Asparagus should always be thoroughly drained. When wet and retentive many roots perish every winter, and the plants are never satisfactory. Light manures, such as horse droppings and gritty road scrapings, suit Asparagus best. The heavier the soil the more of this should be applied, and river or sea sand added in proportions according to the natural condition of the soil will be found to answer admirably. Wood ashes are good, but coal ashes are worse than useless. They may be placed in the bottom as drainage, but amongst the roots they are injurious.

Asparagus roots do not run deep, but live and feed near the surface, and this should be remembered in making the soil ready. Trenching and deep digging are beneficial in helping to improve and drain the surface, but to manure a piece 2 feet deep or more is a mistake. Enrich the surface by all means and make it as good as possible. Fork or dig large quantities of nourishing manure into it immediately before planting, and the results will invariably be satisfactory.

The time of planting must be determined by the condition of the roots. It is not any advantage to plant long before growth begins, and it is injurious to lift and plant after growth has fully started. The best time is when the stems are commencing growth. In some parts of the country this may be about the end of February, and in others not until the end of March. Recently in looking over some young roots we found them just starting into growth, and they were transplanted on the same day.

Asparagus beds are now out of date. They are a waste of ground, and no benefit to the roots or produce. The most profitable way is to plant row after row on a piece of ground and never trouble about beds. The roots should be planted from 2 to 3 feet apart each way, and only 3 or 4 inches below the surface. Roots from one to two years old will be about 1 foot in diameter. The holes for them must not be less than this, and when placed in them none of the roots should curl up. Lay them flat and put two or three handfuls of sand over each, then finish off with the soil which was taken out. Make this quite firm over the roots, and planting is finished.

Older roots which have been planted some years are always benefited by top-dressing in winter and spring. A good handful of salt, guano, or a mixture of both may be shaken over each crown at present with advantage to what is coming in the way of heads. Forking amongst the roots should never be allowed. If the crowns have been mulched throughout the winter this covering may be taken off, placed between the rows and forked in, but to try and work this amongst the roots would end in breaking many of them, and probably injure many of the crowns. Old plantations which have long since seen their best days should not be preserved. They are the reverse of profitable. Cut them to the last this year and then destroy them. Make a new plantation now in fresh ground, and the improvement in quality will soon be noticeable.

Owners of young plantations are often puzzled as to when to begin to cut Asparagus. Must it be two, three, or four years old? Our plan is to cut as soon as the "grass" produced is strong enough to use. Two-year-old plants will sometimes throw up heads which are cut without fear, but poor roots badly managed would show nothing worth having for a long time. Leaving the weak and cutting the strong is a good method. Were they all left the strong would remain so throughout, and the small ones would never come to anything. By cutting and using the finest the small growths are forced to develop, and so a crop is obtained and the plantation is constantly improving.—J. MUIR.

LIME IN FRUIT BORDERS.

THERE is no doubt that lime will be more frequently applied to fruit borders in the future than it has been in the past, Mr. Taylor's useful little book having effectually called attention to its value. Lime appears to have a threefold action upon soil to which it is applied. In its caustic state it liberates from the soil nitrogen, which before its application was not available for plant food. It also is in itself an indispensable plant food, and in its mild state it absorbs nitrogen from the atmosphere. It is of the latter effect which I wish to write. More than twenty-five years ago Professor Nesbit drew attention to the importance of lime in the formation of nitrates. In a lecture on the "Nature and Application of Manures" he said, "Let me further observe that there ought to be calcareous matter in all your soils. There is plenty of it in many districts in the form of chalk, limestone, marl, &c.; and in warm weather there is a process of absorption of ammonia in the air going on naturally in these soils, the ammonia as it is absorbed being converted into nitric acid." Again, in a letter he said, "Whenever animal or vegetable matter—gaseous, liquid, or solid—containing nitrogen comes into contact with mild calcareous or alkaline earths, the mixture being moist and so porous that the air can penetrate, after some time the nitrogen, under certain conditions of temperature, is acted upon by the atmosphere, is oxidised and converted into nitric acid, which at once unites with the calcareous or alkaline bases in the mixture. The temperature most suitable is from 58° to 68° Fahr., and the action ceases at the freezing point."

This is an important matter when we remember that ammonia is the most volatile of all the constituents of manure, and if a dressing of chalk or mild lime will arrest and hold it in a form suitable for plant food by all means let it be employed. Years ago I had proof of the power of spent lime to absorb gases by placing a bucket of whitewash in a shed adjoining a cesspool. When the whitewash was again brought out it was very strongly impregnated with the fumes from the cesspool, and smelt very offensively for some time after. Our fruit houses where the borders are inside seem to present very favourable conditions for this process. The borders are mostly well drained and formed of soil possessing considerable absorptive power; the rubble beneath insures a passage of air, and the temperature is often between the figures named. Add to these the fact that the atmosphere is often charged with ammoniacal gas from liquid placed in the evaporating pans, and it will at once be seen that a dressing of chalk or spent lime must cause a very considerable manurial gain.

Mr. Taylor, in "Vines at Longleat," and the late "Single-handed" in this paper, have given proof that lime can only be kept in soil by frequent applications, and if that is the case in open fields and gardens, fruit borders that have not recently had a dressing must be nearly deficient altogether of this element. We have this year given both Vine and Peach borders a dressing of lime, and all large plants except Azaleas have a share of old plaster mixed with the soil as potting is done. In potting a large specimen of *Adiantum farleyense* which had not been disturbed for three or four years it was noticed that roots were most abundant in the ball where a few pieces of old mortar had been placed at the last potting.—T. A. B.

PRIMULA HARBINGER.

SOME few weeks ago I was favoured with half a dozen strong plants of this lovely Primrose from Mr. Gilbert, with the request to pot and place them in a cold frame with a view to secure a fine display of bloom in March. The plants being strong, clumps were placed in 6-inch pots, the smallest size they could be got into without interfering with the roots. They were placed on a shelf in a Peach house in a light airy position, and in company with a number of *Primula sinensis* both single and double of the choicest strains as regards the singles, including Veitch's Superb Fringed, red and white; Veitch's Scarlet Gem, Williams' Scarlet, Chiswick Red, Waltham White, &c., and in doubles Marchioness of Exeter, White Lady,

Princess Beatrice, Earl of Beaconsfield, Alba plena, &c., and now (the beginning of March) Harbinger is the finest of them all.

I do not know which to admire most—the striking likeness of the plant to the common Primrose, or the refinement of the flowers. Everyone who sees it asks, What is this? I am quite charmed with it as a decorative plant, and being hardy no protection is needed, yet is all the better for a slight protection at the flowering season. What also is lovelier than well-flowered plants of *P. obconica* with its lilac flowers in profusion all through the winter months? Or the pure white of *P. viscosa nivalis* with its immense trusses and fragrance, the yellow and fragrant *P. verticillata*, the large heads of indigo-purple flowers of *P. capitata*, the bluish-lilac flowers in their numerous umbels of *P. denticulata*, or the rich violet-blue with the yellow-eyed flowers in globular umbels of *P. denticulata capitata*, to say nothing of *P. Sieboldi* vars., and the double varieties of *P. acaulis*, and Alpine Auriculas, all of which are beautiful plants for pots, only needing the protection of a frame to have them in flower at an early season.

Harbinger has the foliage and habit of our common Primrose, and is apparently of very free vigorous growth. The plants in 6-inch pots are over 15 inches in diameter. The flowers are borne in loose heads or umbels, having usually ten flowers in an umbel. The plants have thirty flower heads each, and one plant in a 6-inch pot has 360 flowers. The plant is very compact, the flower heads forming a half ball. The flowers appear as a refined Primrose, are perfectly flat, quite circular, without indent, serrature, or fringe on the edge, being quite smooth, of good substance, large (over $1\frac{1}{2}$ inch across), and the colour is white with a faint tinge of primrose. It is a really good variety, and must become popular in every garden.—G. ABBEY.

MANURES AND THEIR ACTION.

HAVING shown on page 149 of the Journal that it is quite as essential for plants to have a constant supply of suitable food for their existence as it is for animals to be fed, and that they obtain that supply chiefly from the soil in which they grow, I will now briefly note how plant food can be added to the soil by the application of various manures, and thus meet the second part of "Querist's" question when he asks what the various manures are composed of, and in what way they are beneficial to plant life. First, it will be seen that if the soil is constantly being deprived of the plant food it contains, and nothing be given to it in return, it is quite possible for the soil to be rendered unproductive and the land exhausted. This evil can be overcome by adding to the land such food as the plant requires in the form of manure. Manures can be classed as general and special, the former being a manure which contains all the ingredients necessary for plant food, the latter one which is applied for a special ingredient contained therein.

There is only one general manure—viz., farmyard manure, which if really good is a perfect food for a plant. The application of farmyard manure is really returning to the land a portion of that which has been previously borrowed from it. The quality may, however, differ under various circumstances, as, for instance, the age of the animal from which it is obtained or according to the management during and after the accumulation. Young animals while growing require a greater amount of nitrogen for the formation of muscle, &c., and phosphorus for the formation of bone; therefore the manure of an old animal has a larger amount of both nitrogen and phosphorus than that of a young one. Then, again, if during its accumulation too much water is allowed to fall on to it the ammonia is washed away, or if fermentation is allowed to take place too rapidly the ammonia escapes. The successful fermentation of the manure heap depends chiefly upon the temperature at which it is allowed to proceed. If the ferment does not exceed 80° no ammonia is escaping. To have good farmyard manure we must have good food, good litter, prevent waste of urine, overheating, and waste by storm water.

Some crops, however, require a greater supply of one kind of food than they do of another, and therefore exhaust the land of that ingredient, and it is found necessary to apply a manure which is rich in that compound or element. A special manure is then used, such as lime, bones, or guano. Lime is one of the ingredients which forms part of the structure of the plant. It also improves the physical properties of land, making clay soils easier to work and less retentive of water. There are three kinds of lime—carbonate of lime (limestone), caustic lime (calcined lime), and hydrate of lime (slaked lime). As a general rule, it may be taken that caustic lime should not be applied to land if there is a scarcity of vegetable matter in the soil, because it will exhaust the organic matter present; but it should be applied in the form of chalk or marl, which contain a large amount of lime. If the soil be heavy and tenacious, then the lime should be applied in the caustic form.

If the phosphorus becomes exhausted in a soil ground bones are applied, as their principal ingredient is phosphate of lime. Bones contain bone cartilage (or organic matter, containing nitrogen, which will produce fermentation), 33.3 per cent; tricalcic phosphate, 55.45; carbonate of lime, 3.85; oxide of lime, 2.90; phosphate of magnesia, 2.05; soda and salt, 2.45.

If ammonia be the required ingredient Peruvian guano takes the principal position. Guano also contains a quantity of phosphorus. This manure is the excrement of sea fowls found on the islands off the coast of Peru. The richest deposits were used first, and consequently much of the present supply only contains 8 or 10 per cent. of ammonia, while in 1855 the average was about 17 per cent.—UNDER GARDENER.

NOTES ON ORCHIDS.

DENDROBIUM LUTEOLUM.—This is a beautiful and useful Orchid, with slender pseudo-bulbs 2 feet or more in length, from which are produced its cream-coloured flowers in twos and threes along the stem just as the plant is completing growth. The throat is blotched with a deeper shade of yellow, which is delicately pencilled with rosy-pink. The lip is large and well thrown back, while the sepals and petals stand forward and give to the flower a distinct appearance. The blooms last for a month, and are freely produced during the autumn and winter. They are very suitable for buttonholes and bouquets. After flowering a good season of rest is necessary to successful cultivation. Most winter and spring-flowering Dendrobies require well ripening and a good season of rest to secure a supply of bloom; but *D. luteolum* makes its growth, flowers, and then requires its rest, which is as essential to success as it is in the case of those kinds that need to be well ripened and rested to flower well.

Plants just past flowering will still have fresh foliage, which will soon ripen as the plants are kept drier at the roots. It is deciduous, and when well ripened should be placed in a cool house for a time, where it more thoroughly rests than if kept in heat. While growing it needs abundance of heat and moisture, and should be grown in a basket suspended from the roof. Like all Dendrobies, it requires shade from the burning rays of the sun while making its growth, but should have a light position, as upon this depends whether the plants are well or poorly bloomed. The time of flowering can be regulated so as to maintain a lengthened supply of bloom, and this accomplished by starting the plants into growth at intervals of about a month. Very little rooting material is needed, and it will do well in peat fibre and lumps of charcoal. It is very liable to attacks of red spider and thrips in a dry or unsuitable atmosphere. Strong plants increase freely by forming growths along the ripened pseudo-bulbs of the previous year. Under artificial light the flowers appear pure white.

DENDROBIUM WARDIANUM.—Those who have only seen this variety with puny pseudo-bulbs and a few small flowers can form no true idea of the beauty of a number of well-grown and profusely flowered plants. Under good treatment it makes pseudo-bulbs 3 feet in length, and these, if well-ripened, will produce two and three flowers from every joint for a length of 18 inches or 2 feet. A number of plants with from three to six flowering pseudo-bulbs upon them, give, when in flower, to any house in which they are arranged, a highly effective appearance, whether suspended in baskets from the roof or grown in pots. They are best in baskets, as their growths are pendant or partially so, and if allowed to hang from the baskets naturally they are more pleasing and ornamental than if stiffly staked. No Dendrobic is of easier culture. If this species is grown in baskets the plants will do well in either all moss or peat fibre, with portions of crocks or charcoal intermixed. I use both moss and fibre, the latter inside and the former on the surface, because from this position it is readily removed annually as the roots commence action. From the time the roots are growing freely to the time the pseudo-bulbs cease extending they should always have a sufficient supply of water. Stimulants applied in the form of liquid manure will be found beneficial if given occasionally in a weak state. No better position can be found for this Orchid than the stove, and the temperature and conditions of a vinery at work will also suit them admirably.

CYPRIPEDIUM VILLOSUM.—One of the best species that can be grown for the conservatory. The blooms will last in such positions longer than those of *C. insigne*. If these two and *C. venustum* are grown they will yield plants for the conservatory for at least a period of eight months. *C. villosum* will flower in this position for three months, and the blooms possess more substance and are brighter in colour when developed in a light temperature of 45° than when they are allowed to open in heat. It will do well in a cool house, but its progress under cool treatment is slow. Here the winter temperature ranges about 60° at night, and the plants are now ready for the conservatory, where they will remain until the middle of May and then be returned to the heated structure. The plant

are not injured by their three months' cool treatment; on the contrary, they are benefited and enjoy the season of rest. They are never allowed to suffer from an insufficient supply of water. To show the progress made of a plant under this treatment, it was six years ago a small piece in a thumb pot, and is now in a 9-inch pot carrying eight or nine flowers. The growths are strong, and are this year expected to make double breaks.—W. B.

PHALÆNOPSIS SCHILLERIANA.—I send you the terminal inflorescence of a large panicle of *Phalænopsis Schilleriana*, which has borne fifty flowers. It has been in full bloom since February 11th, but having been a week in the drawing-room it has not lasted quite so long as it might have done. The plant has five leaves, varying from 12 to 17 inches in length, and broad and thick in proportion. Taking it all in all it was the finest spike of *P. Schilleriana* I have ever seen.—J. U. S.

[The portion of the panicle received is sufficient to indicate that the inflorescence has been an extremely handsome one, for we rarely see so many flowers on one plant, but in this case it is evidently a strong one. Unfortunately *Phalænopsis* are very apt to suffer greatly from excessive flowering. We recently saw a collection which has been removed from a smoky town garden to an open situation in the suburbs, and though the quality and number of the flowers had much improved, the plants were not so strong, and did not make such vigorous foliage as they had done in their apparently less favourable quarters. This was apparently due to the fact that the fogs and smoke caused most of the flowers to fall before they had fully expanded when the plants were in the town garden, whereas in their present more favourable situation the flowers were retained and developed. Beautiful indeed as the flowers appear on the plants, it is a decided advantage if they are cut after they have been open a few days, and in the case of weakly plants it is advisable to remove the spikes as they show.]

CUTTING DOWN DENDROBIUMS.—I enclose two growths of *Dendrobium nobile* taken from a plant in a small pot; one growth has thirty-one blooms expanded, and the other twenty-eight. On the same plant are several more pseudo-bulbs with blooms varying from twenty to thirty on each, in all about 300 blooms. As all our flowers have to be cut and sent 155 miles by rail I find it best to cut off the growths close to the pot, when the young growths start from the bottom. In this way I get from a dozen and a half to two dozen growths on each plant, varying from 18 inches to 3 feet in length, bloomed like those enclosed, which make a grand display and are useful for cutting.—B

[Finer examples of this grand old *Dendrobium* we have never seen. One of the pseudo-bulbs has twenty-eight flowers in a space of 8 inches, three or four being produced from a node. The flowers, too, are of good size and excellent colour. We shall be glad to receive notes or specimens of good Orchids from any of our correspondents.]

PRESENT AND PAST METHODS OF CULTURE.—Orchid growers will perceive with pleasure that space is now set apart in the pages of the *Journal* for notes and gleanings about Orchids. To record successes and failures and discuss methods of cultivation assist very largely towards the discovery of the best and easiest method, and in that department of horticulture which is devoted to the great Orchid family this is especially the case. Many of us remember what Orchid-growing meant before the nature and habits of the plants were properly understood; most of us are aware now that by far the larger proportion of Orchids are among the least difficult of plants to manage. Instead of specially constructed houses, specially trained and specially paid men being necessary to success in Orchid management, we have learnt that success is achievable without wandering far beyond the lines of ordinary gardening routine. *Dendrobiums* as strong and healthy as Bamboos are now grown in vineries; *Celogynes*, *Cypripediums*, and a host of other kinds are cultivated in stoves with the mixed stove plants. *Odontoglossums* are grown by thousands in frames and pits, where they are treated to the hose or rose-pot in a way that would horrify an Orchid grower of the old school. These are a few instances of what is done in the management of Orchids, but they are sufficient to show what perseverance and experiment have done towards simplifying the cultivation of Orchids. Much has been done, but much still remains to be learnt before we can feel satisfied with all our Orchid pets, and so it is that we are always on the look-out for information which shall help us in the management of those plants whose requirements are at present but imperfectly under-

stood. For my own part I hope to glean much from our Orchid column, and I also hope that by recording whatever is noteworthy I shall be able to assist others over little difficulties which are ever arising when we are dealing with new or delicate plants.

WATERING ORCHIDS.—Speaking of the use of the hose for watering *Odontoglossums* recalls the practice of Messrs. Sander and Co. in their treatment of *Cattleyas*. In the new houses at St. Albans may be seen thousands of these plants arranged in such a way as to suggest a long street, and in the summer these plants are watered, not by means of a small pot through which water is carefully dribbled, but a hose pipe is used, and a thorough sousing overhead, a saturating one might say, is given almost daily. Of course in the winter less water is given, though the plants are never allowed to become as parched as one sees *Cattleyas* treated now and then. That Messrs. Sander & Co.'s plants thrive upon this daily ablution may be seen by visiting their houses. I took the hint, and since then have watered and syringed our *Cattleyas* in a way that would have made me wince once, and I am so satisfied with the result that I intend for the future to water all our *Cattleyas* as freely as *Crotons*. Given a healthy plant, proper drainage and good soil, or rather peat fibre, there is no reason why *Cattleyas* should not receive abundance of water when growing and be kept moist all through the winter. If the ventilating and shading are right—and almost everything depends upon these—there can be no fear of immature growth or damping of flower sheaths.

LIQUID MANURE FOR ORCHIDS.—Last year our plants of *Odontoglossum vexillarium* and *O. Phalænopsis* were watered very heavily, and they are now better than we could grow them when water was sparingly supplied. I know a gardener who grows these two *Odontoglossums* and *O. Roezlii* in a green house along with *Bouvardias* and similar plants. They are potted in pure sphagnum and placed on a shelf about 2 feet from the glass, where they are shaded from bright sunshine, and where they have plenty of fresh air without experiencing any cold draughts. All through the summer the watering pot is used freely, and once a fortnight a weak solution of cow manure is applied to the roots. To prevent the great enemy of these plants—thrips—from gaining a footing, my friend dips his *Odontoglossums* in soapsuds as often as he supplies them with the liquid manure. Now these plants are like sedges, healthy, dark green, spotless, and as ripe and plump as acorns, and when they flower they are pictures of health and beauty. That idea of using soapsuds and cow manure was culled from a paper note. At an Orchid sale recently I saw a plant of *O. Phalænopsis* in an 8-inch pot with ninety pseudo-bulbs, and leaves without a spot. I failed to discover the grower of this plant, but I wondered whether soapsuds and cow manure had anything to do with it. Orchids are most of them capable of adapting themselves to conditions slightly altered from what they thrive naturally under, and they are also capable of being successfully managed under artificial treatment varying somewhat in its details, so that when once we have the key to the secret of their health we may be able to produce equally good results from slightly different methods. I say this because I know others who grow these plants well without having recourse to the specifics of my gardening friend.—W. W.

FLOWER SHOW SCHEDULES.

In the *Journal* of February 21st, page 144, you publish under the above heading some remarks on the "suicidal course" and "selfishness" of the Eastbourne Gardeners' and Cottagers' Society in not throwing their society open. I believe I can put the matter in a very different light, and show that the "selfishness" is on the side of the writer, Mr. J. Gore. This Society was formed about four years ago "for the general diffusion of knowledge amongst its members relating to the cultivation of fruits, flowers, vegetables, &c." Monthly meetings are held, at which papers on horticultural subjects are read and discussed. Mr. Gore, although aware of the existence of the Society, had no wish to become a member until he saw the schedule of the summer Show last year, and as the members were satisfied that he had no idea of benefiting the Society by attending the monthly meetings the resolution to which he refers was passed.

His remarks as to the entrance fees and members' classes are, to say the least, misleading. There was one entrance fee of 5s. in Class 1, where £18 was offered. Altogether £140 was offered in prizes. Of this amount £95 was open to Mr. Gore; £19 only was reserved for professional members. The remainder was for amateurs and cottagers, and I fancy even your correspondent would hardly expect to compete with them. The amount reserved for members is surely no more than they are entitled to, as they give a great amount of time and trouble to further the objects for which the Society was formed, and also, owing to the climate and soil here, they cannot compete equally with gardeners further inland.

I forward by this post schedule of Show and copy of rules. You will see by the first rule the objects of the Society, and that shows are only a

secondary consideration I think is clear by Rule 22, the last but one. I must apologise for so long a letter, but as no one knows better than I do the good this Society has done and is doing I cannot allow such misleading remarks to remain uncontradicted.—HENRY WOOD, *President of the Eastbourne Gardeners' and Cottagers' Society*.

[In only one of the twenty-three rules is there any allusion to exhibitions, and this only states they "may be held in Eastbourne if approved of at a general meeting, at which the production of the members shall be shown." Rule 16 shows that an excellent object of this Society is to assist destitute members, and to aid those unemployed to procure employment.]

VIOLET COMTE BRAZZA.

WHEN Mr. Allan, gardener to Lord Suffield, Gunton Park, Norwich, exhibited before the Floral Committee of the Royal Horticultural Society,

panying engraving) gives the following description of the plant, which well expresses its chief characters. "Since the plant came into my hands from the famous Italian garden of Count Brazza de Savorgnin, I have had ample opportunity of testing its merits, and have put it through a most exhaustive critical and complete trial with splendid results. In character it partakes of the style of the favourite winter-flowering variety Neapolitan; this fact alone shows its great superiority over other double white forms, which are generally more or less shy and late. The flowers are thoroughly double and very large, attaining under good cultivation to the extraordinary diameter of $1\frac{1}{2}$ inch, and are often composed of as many as forty petals. They are borne on long vigorous stems, rendering it specially fitted for cutting, and the colour is pure white, while the scent is most powerful and delicious."

Fig. 44.—VIOLET COMTE BRAZZA.

ovember 13th, 1883, a number of flowers of this handsome Violet in comparison with the old Neapolitan and Marie Louise, they were much admired, and a first-class certificate was readily granted for the variety. Since then flowers have been shown on several occasions, and the valuable qualities which distinguished the first have been so well maintained that it has obtained a firm hold on popular favour. Violets are liked by everyone, and it is therefore not surprising that a variety with large well-formed double pure white fragrant flowers should be so heartily welcomed.

Mr. T. S. Ware, Tottenham (to whom we are indebted for the accom-

Samples of the Tottenham flowers were submitted to us a short time since, and were in size and purity some of the finest we have seen.

FRUIT TREE CANKER AND ITS CAUSES.

I READILY endorse what your correspondent "R. P. B." says on this subject (page 168) as to the soil affecting Apple trees in such a way as to produce canker. I feel sure he is correct in stating that to be the chief cause, and no doubt he is also right in advocating keeping the soil firm for fruit culture. If it does not tend to check canker, it will prove of much benefit generally to the trees and also to the crop they produce. The less the roots are interfered with after the trees become established

the better, unless it be found necessary to root-prune them, and this will not require to be done so frequently where the soil is kept firm around the trees as where it is regularly forked. We find here (Hertfordshire) shallow planting the best means of preventing canker. This, combined with judicious root-pruning at the time of planting, will ward off canker for a great number of years. All roots tending downwards should be pruned very much harder than lateral ones. Each tree should be elevated in planting in such a manner that when the operation is completed they should stand on mounds a few inches above the level of the ground around them, and all the lateral roots should be spread out carefully as near the surface of the soil as possible. If the soil be of ordinary good quality no manure need be put in with it, as it is far better to apply it as a heavy top-dressing, which will have the effect of encouraging the roots to keep near the surface. After careful labelling with permanent labels, such as the Acme fruit tree label, and firmly staking each tree, keeping down weeds by hoeing and hand-weeding, nothing more will be found necessary until the time arrives for another top-dressing, which should be applied in February, or March at the latest.

The soil of different localities appears to affect some varieties in a marked manner. For instance, we have Potts' Seedling Apple worked here for a number of years, and all the trees are in the best of health, whilst some trees of this variety we recently procured from Lancashire are all more or less affected. Dumelow's Seedling, or Wellington, succeeds here wonderfully well, and is very free from this dread disease, whilst I have noticed in some parts of Hertfordshire this same variety suffers most severely. Lord Suffield generally cankers as soon as the roots get down to the subsoil; on the other hand, Lord Grosvenor remains perfectly healthy. This latter variety bids fair to be extensively planted in preference to the former. Ecklinville Seedling is one of the most healthy and vigorous-growing varieties of Apple we have, rarely if ever showing any sign of canker, and a most prodigious and constant cropping variety. Cellini is a great cropper, but as soon as it reaches the subsoil it cankers badly. Herefordshire Beefing is a vigorous grower, and is undoubtedly very free from canker; it will keep in good condition till June, and is a large and constant bearer.

Would it not prove of great advantage to a large number of your readers, now that Apple tree planting is so much on the increase all over the country, if you could obtain from reliable sources lists for publication of varieties best suited to cultivate in various districts, and such as are least liable to canker? Such information would be much appreciated by a number of readers of your valuable Journal.—H. R. ILLMAN, *Hereford*.

WHEN reading the notes on this subject (page 168) by "A Yorkshire Gardener" and others (page 168) I was reminded of a few notes in an old diary of observations taken by me at different times and places, which I submit for your readers' judgment should you think them of any service. When graduating in a certain garden in Lanarkshire I noticed that during my time no ground was dug near fruit trees. An alley, as we call it, was left 3 feet from the walls on which trained Peach, Pear, and Plum trees were. The garden soil was decidedly heavy, with a wet subsoil. Also near Derby the same rule was observed with regard to fruit trees, and canker in both cases was unknown. Here (Cavan) the case is altered, as we have not an Apple or Plum that is not affected with this disease. It cannot be from imperfect drainage, as the garden soil is like a river's bed with pebbles resting on the rock (iron). Trees planted twelve years ago could be easily pulled up by the roots. I may say I have never seen a case of canker in old orchards that are laid out in grass. Has any other observer seen it there?—RITCHIE.

HARDY PLANTS IN FLOWER.

SISYRINCHIUM GRANDIFLORUM.—A charming spring-flowering plant, so delicate in appearance, yet so capable of holding its own against driving rains and winds. One thing is certain, it dislikes a dry position, and has an equal aversion to light soils such as peat. The best plants I possess are in a damp position with rather heavy loamy soil, and I recently saw some in pots of very stiff soil, the drainage of which was nearly stopped, but the plants were extremely healthy and flowering freely; indeed it is one of the few hardy plants which do really well in pots, and that with limited room. Perhaps the prettiest sight I have seen this season was a clump of this plant mixed with its white-flowered variety. I planted them last year. The pieces of album were rather weak, but they flowered fairly well, and the charming contrast of the intermingled flowers was most pleasing. I find the white-flowered variety rather more delicate, and I think rather later in flowering, although the latter may be due to my plants being weak; but certainly they were not quite so forward as those of the typical form, yet were in sufficient time to associate with some of the latest purple flowers. All lovers of hardy flowers should secure both forms. A few good pots in a greenhouse are very beautiful, as the flowers last well under glass and are quite distinct from most plants employed for that purpose.

SNOWDROPS.—Since writing my last notes I have had the very great pleasure of examining some rare and beautiful forms of *Galanthus nivalis*, the most distinct of which were *G. poculiformis* and *G. lutescens*. The former is very peculiar. The three inner perianth divisions are nearly or quite as long as the other ones, and not arranged in a small cup like the usual form, but are sub-spreading

and quite white throughout, entirely devoid of the green blotches and inside lining, also characteristics of the species, so we may consider it one of the most distinct of all the Snowdrops. The variety *lutescens* is really yellowish, as its name implies. The green blotches of the type are replaced by yellow ones, and the base of the inner divisions is yellow-tinted; hence we have a decided if not a very desirable distinction from the rest. The variation in *G. Elwesii* is very great. I have just had a bulb in flower with the outer divisions very narrow—not more than two lines broad, and sharply reflexed like those of *Narcissus triandrus*. The inner divisions were of the usual character. The flower presented a very queer appearance, but it is most interesting to note these differences, and in this case I shall take special care of the bulb.

LEUCOIUM VERNUM.—With regard to my remarks on this charming bulb on page 148, I am informed there was a variety called *carpathicum* which is thought to be lost to cultivation, and that the main distinguishing characteristics of this variety were a two-flowered peduncle, and yellow spots upon the flowers instead of green. Now, in my notes I stated that the peduncles were from one to three-flowered, and these notes were made from a large bed where perhaps 2000 bulbs were in flower. On looking over the same bed again I find the bulk of them are two-flowered, and only about three scapes with three flowers upon them, from which I shall if possible save seed. In my opinion there is no basis at all for the variety *carpathicum*, because I notice some of the bulbs producing two-flowered peduncles have side bulbs which only produce a solitary flower. Referring again to the colour of the spots as a distinctive mark, is again most misleading, as I notice every gradation from bright yellow to deep green and *vice versa*. I have seen it described as difficult to please—the opposite to this is my experience; it certainly enjoys a rich light sandy soil, and does not like being disturbed, although if the bulbs are fully developed the fact of removing them from one place to another will not prevent their flowering, for in November last I removed over 1000 of such bulbs, and they have flowered grandly, and are now making excellent growth. In the autumn of 1882 I received a large number of bulbs from the continent, which were so very small that up to this time they have not produced a flower, neither do I believe they would had they been kept undisturbed. *L. pulchellum* is just opening its flowers, but I do not think them so pretty as those of *L. vernum*; they are not so large, but more numerous, pure white with green spots; a clump of it is very desirable so early in the year.

GLORY OF THE SNOW (*CHIONODOXA LUCILLÆ*).—This is certainly one of the most charming spring-flowering bulbs. There is a white-flowered variety, but I do not think it an acquisition, nor perhaps so showy as the old *Triteleia uniflora*, now flowering freely. Many have expressed themselves disappointed at the "Glory of the Snow," but I think this is mainly due to the fact of its infancy in our gardens. Wait until we have well-established clumps and then everybody will be pleased. Those bulbs which have been in the ground three years are very much stronger, they produce much finer spikes of flowers, and the individual flowers are larger. The bulk of the purchasers have been supplied with small imported bulbs up to the present, which are only capable of producing one or two flowers, and those bulbs may be freely mixed with *Scilla bifolia* and *Galanthus Elwesii*. In due time we shall have strong home-grown bulbs, and the results I feel sure will be more satisfactory. It seems quite hardy, but it likes a well-drained position in rich but light soil. I have several bulbs pricked in crannies of the rockery, and these have some very fine spikes, and they look extremely pretty nestled against the stones; indeed, it is a very fitting home for them, as they are quite capable of taking care of themselves if left undisturbed, and they bloom at a time when most occupants of the rockery are but just awaking from the sleep of winter; and by the time that such are rampant in growth the *Chionodoxa* has passed to rest.

DONDIA EPIPACTIS.—This is not a very attractive plant, but I am always delighted to see its curious little yellow heads peeped out just above the ground. It likes a damp position, hence the best tuft I have is at the foot of a damp rockery, where it is evidently very happy, and is now crowded with flower heads.

LEONTICE ALTAICA.—A very rare plant, closely allied to the *Corydalis*, and it might easily be mistaken for one. I am not sure that it is perfectly hardy in all parts of the country. I do not risk my plant outside, but give it the protection of a handlight, so that it is kept dry during the autumn and winter; and it is planted in a well-drained position in light sandy soil. It produces freely divided glaucous leaves, and racemes of bright yellow flowers. It is a native of Siberia, and was introduced as early as 1818, but was evidently nearly lost to cultivation until Dr. E. Regel of the Imperial Botanic Gardens, St. Petersburg, replenished the small stock in this country a few years since. It is flowering rather early this season, owing undoubtedly to the extreme mildness thereof, and the fact of its being covered with glass. It is not the plant for everybody to seek, but it

is one of those plants which heighten the enjoyment of the cultivator whose love for plants stimulates him far beyond the desire to insure brilliant colour or striking effect.

DOUBLE PRIMROSES.—These please everybody. Well, perhaps I am going beyond the mark, because I heard a fastidious individual the other day remark, when his attention was drawn to some of these flowers, "Oh! I don't care for double flowers." But they like double Primroses in Ireland. When there last year I was greatly struck at the number of them grown, and how luxuriantly they flourished. Pompadour is there in abundance, blooming most profusely. This has the richest of all colours in Primroses; but there are two varieties, at least I think so, one is rich crimson throughout and rather more double than the other, which is yellowish at the base of the floral leaves. I prefer the former, as I think it flowers more freely than the latter. Then there are double white, sulphur, yellow, rose, red, and purple, all of which are extremely free-flowering and very handsome; and if covered with glass, and thus kept clean, the flowers are very useful in a cut state for many purposes. From Messrs. Fröbel and Co., Zurich, has come a hose-in-hose Polyanthus of a rich scarlet colour under the name of *Primula veris coccinea plena*. It is very free-flowering and showy; indeed, more so than any other similar form of Polyanthus I have seen. Mr. Cannell speaks highly of some of his varieties, but those I have never seen; but most likely they are all very pretty. There is one double Primrose I have under the name of "Scotch." Whether there is such a variety I do not know; the flowers are of a rich rose-purple colour, yellowish at the base, and very freely produced. I have heard of one in Ireland under the name of "Sapphire," which is said to be very scarce, of a deep bluish purple colour. I wonder whether any of your Hibernian readers could give us any information respecting it.—T.

At a general meeting of the ROYAL HORTICULTURAL SOCIETY, held last Tuesday, Maxwell T. Masters, Esq., M.D., F.R.S., in the chair, the following candidates were unanimously elected Fellows—viz., Frederick Henley Newens, R. P. Percival, F. Sander, George Cappelen Sawyer, Charles Sharpe, Sir Henry Thring, K.C.B., Mrs. Arthur Tower, Mrs. Tremlett. The President, Lord Aberdare, has nominated the following gentlemen Vice-Presidents for the ensuing year—viz., Sir Trevor Lawrence, Bart., M.P., J. H. Mangles, Robert Hogg, LL.D., F.L.S., Sir P. Cunliffe Owen, K.C.M.G., C.B., C.I.E.

— WE regret to learn that DR. GEORGE ENGELMANN, who has gained so great a fame as a botanist and an authority on Conifers, died, at the age of seventy-five years, on February 4th, at St. Louis, in Missouri. He was a native of Frankfort-on-the-Maine, but has spent most of his life in the United States, where he has carefully studied the Conifers, Cactæ, and Agaves. His magnificent book upon the Cactaceæ of the Boundary Survey Expedition was one of his principal works, several treatises and essays having also been published.

— MR. WRIGHT begs to acknowledge the receipt of £3 10s. 6d. that was generously contributed for the benefit of MRS. HONEYMAN by the members attending the meeting of the Manchester Horticultural Mutual Improvement Society, held on the 6th inst., and transmitted by Mr. W. Swan of Oakley, Fallowfield. "A Gardener's Wife" has with equal generosity sent 10s. and a kindly sympathetic letter. A correspondent has also sent 5s., which he "neither wants acknowledging publicly nor in any other way." He will perceive that it has been received, and this, with the other contributions, are thankfully accepted.

— MR. EDWARD MAWLEY's annual contribution to meteorological literature is now issued (Stanford), and "THE WEATHER OF 1883" contains a series of elaborate observations on the variations in temperature, rainfall, barometric pressure, wind, duration of sunshine, &c., which are recorded in the same full and accurate manner which has distinguished previous issues of the work. A table is also given comparing 1883 with 1882, from which it appears that the chief difference is in the rainfall of the past year exceeding that of the preceding one by over 2 inches.

— "MR. PERKINS, the Secretary of Lord's Cricket Ground, says

he has a plague of the grub of the 'DADDY LONGLEGS,' and that they are ruining the grass. Can anything be done? I hear Regent's Park grass is bare through them." Thus writes a correspondent, and we are sorry to hear of such a violent attack of this destructive and almost ineradicable pest. We would suggest that Mr. Perkins make a few experiments with petroleum, by mixing from 1 to 3 or 4 ozs. of oil with water, and trying the effects of different strengths on separate plots. It is possible that he may ascertain the right quantity to use, so as to check, if not destroy, the larvæ, and at the same time benefit the grass. It must be remembered that the oil and water can only be incorporated by constant and violent agitation when the solution is being used; if not agitated the petroleum floats on the water. Solutions of hellebore might also be tried, mixing from 2 to 4 ozs. of powder into a paste, then adding a little boiling water, which can be cooled and increased to a gallon with cold water.

— **GARDENING APPOINTMENT.**—Mr. Richard Parker, foreman under Mr. McIndoe, at Hutton Hall, Guisborough, has been appointed to succeed Mr. Owen Thomas as gardener to John Corbett, Esq., M.P., Impney, Droitwich.

— "IPSWICH" writes in reply to "A. M.," page 166, relative to WASHING VINE RODS, that he does precisely what he advised—namely, uses a spoke brush as quickly and vigorously as a groom uses it in washing a carriage. He does not pretend to keep the water at any given temperature, as if it is applied at any heat between 120° and 160° to Vine rods when they are quite at rest, he does no injury to them whatever; while if it does not destroy all the insects and eggs in the bark, it is the fault of the workman. Provided the work is quickly done, and boiling water can be had by walking fifty or even a hundred yards for it, there is no difficulty in maintaining the temperature indicated of that which is applied to the Vines.

— As will be seen by an advertisement in another column, arrangements have been made by the Council of the Royal Horticultural Society for holding a CONFERENCE ON THE NARCISSUS on April 1st, at which Mr. F. W. Burbidge will read a paper, which is expected to lead to an interesting and instructive discussion on the large and popular genus to which it pertains.

— MESSRS. JAMES CARTER & Co. have sent us a pamphlet on laying down and improving lawns, lawn tennis, and cricket grounds, the perusal of which may be useful to persons interested in the subject.

— AT the ordinary meeting of the ROYAL METEOROLOGICAL SOCIETY, to be held at 25, Great George Street, Westminster, on Wednesday, the 21st inst., at 7 P.M., the following paper will be read:—"Brief Notes on the History of Thermometers," by Robert H. Scott, M.A., F.R.S., President. After the reading of this paper the meeting will be adjourned in order to afford the Fellows and their friends an opportunity of inspecting the exhibition of thermometers and of such new instruments as have been invented and first constructed since the last Exhibition.

— MR. J. SIMPSON, Wortley, writes respecting PEACH TREE EXTENSION:—"I am always pleased to answer any *bonâ fide* questions that may be asked me on this subject, and I have answered many; but if 'A Working Gardener' (page 189) will again refer to the source where he found I 'claimed credit as being' not 'the author' of the extension system, but the first to 'practise and recommend it on definite principles,' he will find all the information he now seeks minutely given and illustrated; also that 'extension' is not what he would make it appear to be, and that it does not refer to either the size or the number of trees so much as to the raising and fruiting of them soon and successfully."

— THE LINCOLN CHRYSANTHEMUM SOCIETY announce that their second Exhibition will be held on Tuesday and Wednesday, November 18th and 19th of the present year, in the Corn Exchange, Lincoln. The first Show was successful, and the Society has secured a balance of £29 19s. 9d. in its favour—very encouraging results. In the schedule now being issued thirty-one classes are enumerated for specimen plants and cut blooms.

— "C. W.," writing in regard to CONTROVERSY, observes:—"I trust the readers of the Journal will duly appreciate the eminent abilities and fully recognise the high position to which "Casual" (page 83) has attained in respect to the subtle rules and laws of controversy. As the mantle of the modern "Draco," whom he so freely, so forcibly, if not so wisely, quotes, has unquestionably fallen upon his own shoulders, he

should endeavour to exercise some forbearance towards those who have not had such exceptional teaching, nor such an inimitable teacher. From his concluding, I cannot say conclusive, sentence, I am again tempted to ask, Does he really mean to infer that the young shoots and leaves of the Vines referred to subsisted on the contents of the bottles only?"

— MR. E. LUCKHURST writes:—"I had a plant of CLEMATIS COCCINEA last spring which I kept in a pot throughout the year. It grew freely and produced several of its curious bell-like flowers, which, although not quite answering to its title of 'Scarlet Clematis,' were yet sufficiently novel and attractive, with an orange interior and bright vermilion exterior, to render it a welcome acquisition both for pot culture and for an open wall. It has been described as growing 5 to 6 feet high; but I have also seen it stated that it makes a stout annual growth directly from the crown of 10 feet, which dies down in autumn, so that it will be useful to mingle with other climbers at the base of lofty buildings, and also answer for mixed collections on walls. I have recently been able to devote some wall space to the trial of novelties, and intend now planting this Clematis there, and hope soon to know more about its real value as a decorative plant."

— THE same correspondent observes that "The valuable evergreen climber AZARA MICROPHYLLA is now in full bloom. Its flowers are hardly visible unless we look closely for them, being very small, and produced on the lower side of the branches in clusters at the axil of every leaf; they are yellow, and have a decided vanilla perfume. If the orange-red berries come as thickly as the flowers this season they will afford a striking contrast to the dark green glossy foliage, and add considerably to its already attractive appearance. The arrangement of its foliage is very curious; it comes in pairs, one leaf being more than twice as large as the other, the large leaves spread out on either side of the branches and the small ones turn backwards along it, and have such an elegant effect that I have frequently used the long slender sprays among cut flowers. For clothing a wall with perennial greenery it is a most useful shrub. I planted it five years ago against a lofty building facing the west, where it is much exposed to high winds, but it has grown freely, and is in a perfectly healthy flourishing condition."

— PRESENTATION TO DR. SCHOMBURGK.—In September last a meeting was convened of the friends and admirers of Dr. Schomburgk, Curator of the Adelaide Botanic Gardens, for the purpose of considering the best means of practically recognising the valuable services rendered to the colony by that gentleman in the cause of botany. It was then decided that his portrait should be painted and permanently placed in some portion of the Gardens under his care. A committee was formed, subscriptions were obtained, and the task of producing a painting of Dr. Schomburgk was entrusted to Mr. L. E. Tannert, Master of the School of Art. The work was recently finished, and it was decided that a public presentation of the painting should be made to the Board of Governors of the Gardens, and his Excellency the Governor was requested to perform the formal ceremony. January 30th was fixed as the occasion, and on that day the Museum of Economic Botany, situated in the centre of the Gardens, was converted into a temporary hall. The painting was hung over the northern interior door, and bore the following inscription:—"This portrait of Richard Schomburgk, Ph.D., &c., &c., &c., is presented to this Museum by a number of his friends in appreciation of the zeal, energy, and skill which he has devoted to rendering the Botanic Gardens an ornament to the City of Adelaide, and the pride of the Province of South Australia." The Committee also felt that Dr. Schomburgk ought to have something to personally retain as a souvenir of his friends, and with that object they had decided to give him an album address. After an appropriate address by the Governor the portrait was unveiled, and accepted by Dr. Wyatt as the oldest Governor of the Gardens. The Secretary to the Presentation Committee then read the following address, copied from the album:—

To Richard Schomburgk, Dr. Phil., &c.

Dear Sir,—At a general meeting held at the Town Hall, Adelaide, on Friday, the 21st day of September, 1883, it was resolved unanimously:—"That your portrait be painted and placed permanently in the Museum of Botany as a testimonial of your long services, pre-eminent abilities, taste, and zeal as Director of the Botanical Gardens, and that an album containing a suitable address be presented to you." In accordance with such resolution a portrait has this day been so placed, and we solicit your acceptance of this album as a token of our sincere respect and esteem, and as a recognition of your scientific attainments, and of the unsparing exertions you have devoted to rendering the Gardens an ornament to the city of Adelaide, the pride of South Australia, and the admiration of visitors to the colony. We desire to express our opinion that through your efforts and influence a taste for floriculture and the advancement of botany has been permanently established and wishing you long-continued health, prosperity, and happiness.

We are, dear Sir,

[Signed by His Excellency the Governor and about 160 other gentlemen. Dr. Schomburgk, in returning thanks for the well-merited honour, accorded praise to all who had contributed to the success of the Gardens, and the interesting ceremony was brought to a close.]

— THE *Florida Dispatch* states that the HORTICULTURAL HALL AT NEW ORLEANS will be 600 feet in length, having two wings of 250 feet, 100 feet wide, and a central hall 180 feet wide for a distance of 100 feet, surrounded by a dome covered with glass. The sides will be of glass, extending to the main roof, and it is intended to collect and range around the outer edge of the building, inside of the glass, rare collections of plants and shrubbery from Mexico, Central America, the islands, foreign countries, and the United States. A section of the building will be provided with hothouse apparatus for the protection of the choicest and most delicate plants. The double row of plants and flowers extending all around the building will, therefore, cover a distance of 1500 feet. Through the central part of the main hall and the wings the tables for an international fruit display will be ranged sufficient for 20,000 plates of fruit from all parts of the fruit-growing world. Superintendent Earle has nearly completed the premium list for the Pomological Department, which offers awards of about 15,000 dollars.

THE GARDENERS' ROYAL BENEVOLENT INSTITUTION.

In your columns of November 8th last Mr. Divers of Burghley made the following charge against this Institution—viz.,

"A friend of mine paid £10 10s. to this Society, thinking thereby to provide for a rainy day. By-and-by he became seventy years of age and unable to pursue his calling any longer. On applying to be placed on the pension list he says he was told he had paid the £10 10s. as a donation, and consequently was not eligible for the pension."

On November 16th I, by the direction of the Committee, through your paper requested Mr. Divers to favour me with the name and address of his friend, and also if possible with the name of the person who gave the information, in order that they might investigate the matter. Mr. Divers wrote to say he would make inquiry. Three months have elapsed and my Committee have heard nothing further on the subject.

I have been Secretary now over forty-one years, have attended every meeting of the Committee, and have no recollection of any such an occurrence. The old and constant attendants at the Committee meetings have been consulted, and they have no recollection of any such case being brought before them, and I have by the instructions of the Committee carefully searched through their minutes and can find no record of any such transaction.

Is it not contrary to common sense that a man who had paid £10 10s. to the Institution should sit quietly down and put up with the alleged subterfuge? The Committee is composed of twenty-four gentlemen carefully selected for their probity and intelligence, would they condescend to such an equivocation? Why did not the subscriber in question communicate with them individually, making known his wrongs? Are there not numerous subscribers to the Institution to whom he might have appealed? Is there not the gardening Press to whom he might have written? They would have ventilated the subject. And last, but not least, why did he not avail himself of Rule No. 29, which provides that any dispute between a claimant and the Committee shall be referred to arbitration, and the result of the arbitration shall be final? But no, not one of these courses have been adopted, and as Mr. Divers has not favoured the Committee with the information they were anxious to obtain, they can arrive at no other conclusion than that the allegations made by him are totally devoid of foundation.

Before Mr. Divers again allows his pen or his imagination to run riot and bring such an accusation against this Institution, which is conveying comfort and assistance to 104 families, the Committee would ask him to remember the old proverb, "Curses are like young chickens, they come home to roost," and that it is within the bounds of possibility that some day he may be anxious to share in the benefits afforded by this Institution which he has been at such trouble to disparage.—EDW. R. CUTLER, Sec., 14, Tavistock Street, Covent Garden.

THE CURRANT-BUD MITE.

BLACK CURRANT bushes could not be worse attacked by this mite in any part of the country than they are in the neighbourhood of Liverpool. Six years ago I discovered it upon some bushes here, and all the parts affected were burnt. The following pruning time they were worse than when first noticed, and all these infested were removed and clean young plants purchased. Two years after the whole, young and old, had to be uprooted and committed to the flames. Clean stock was again obtained and planted in the kitchen garden some distance away from the old plantation, and ten minutes' walk from any Black Currant bush. The following autumn these were perfectly clean, and were lifted and planted on the ground they were intended to occupy. Long before last autumn they were attacked, and experiments are being tried to rid them of this destructive pest. At the present time I am of opinion—and this is founded upon experience and

observation—that it is useless to try to eradicate the pest if bushes in the neighbourhood within moderate distance are subject to its ravages. The only way that I can see of thoroughly exterminating them would be for all who are troubled with this mite upon their trees to destroy them, and then not plant again, say for twelve months. It is evident they migrate from garden to garden.

I believe that this *Phytoptus Ribis* has established itself in the buds long before the month of November, for the buds may be noticed swelling or “knotting” soon after they are formed along the young wood. Their work of destruction is going on all winter, and by the time the buds should begin to swell the mischief is complete. During the past few years I have examined large numbers of buds during the autumn, winter, and spring months, and found living insects, but never more than one or two in each bud. They are so minute that it is impossible to discern them with the naked eye.—W. BARDNEY.

THE MANCHESTER HORTICULTURAL MUTUAL IMPROVEMENT SOCIETY.

THE closing meeting for the present session of this Society was held on Thursday evening, in one of the rooms of the old Town Hall, King Street. Mr. Bruce Findlay, the President, was in the chair. There was a large attendance of members.

Mr. William Swan, the Secretary, read the report of the Committee for the past session. They congratulated the members upon the work done during this period. The Society was formed in October last. In no way could the objects of the Society be more efficiently accomplished than in becoming, as it were, a centre towards which all the practical improvements made in its vicinity should tend. More than one individual distinguished for love of natural science in general, and of horticulture in particular, had promised to give lectures next session. The number of members at present on the books was 123.

Mr. Robert Tait, the Treasurer, said the session ended with the balance on the right side. The Society started with a financial difficulty because the amount of the subscription, half a crown, was merely nominal. It was thought if they could obtain fifty or sixty members the Society might possibly hold its position, but with the large number of members who had now joined, and with one or two donations, the difficulty was removed. He then proceeded to read his financial statement, which showed that the total amount of subscriptions were £17 10s. 6d., and that after meeting the expenditure there remained a balance in hand of £5 18s. 4d.

Mr. Bruce Findlay moved the adoption of the report and Treasurer's statement. It was gratifying to know, he said, that many young gardeners had attended the meetings during the past session, and it was to be hoped that the number next session would be increased. It was also gratifying to those who had had the work of convening the meetings to know that they had been well attended, and that the lectures were appreciated. The objects of the Society were the improvement and increase of gardeners, and one result would be, he thought, that gentlemen wanting gardeners would apply to the Society for them. In fact, he had before him such an application from a gentleman.

Mr. W. Nield said he had derived much profit and pleasure through attending these meetings. It might be wise to throw out some suggestions as to the kind of papers that should be read before the members at future gatherings. He had found that several members were not in favour of addresses on botanical subjects. He himself was much interested in botany. If they had papers on botanical subjects those members interested in them should be made acquainted with the fact, so that they might attend. Some members thought that they should have nothing but papers of a practical nature.

Mr. Bruce Findlay thought they should vary the subjects as much as possible. Inasmuch as botany was really the foundation of the Society, he thought it would be suicidal to omit botanical subjects, and if such subjects were brought forward evenings would be set apart for them. Mr. Richard Astley maintained that botany and horticulture ought to go hand in hand. If desirable the lessons might be simplified, so that every gardener could understand them. The practical botanist and gardener joined together made the best man in each branch. Mr. William Plant remarked that they as gardeners got very little knowledge from papers on strictly botanical subjects. His idea was that they should try as far as possible in their addresses to combine practical gardening with scientific botany, and thus blend together theory and practice.

The motion for the adoption of the report and Treasurer's statement was then agreed to. It was decided on the motion of Mr. Butterworth, seconded by Mr. Thomas Lunt, and supported by Mr. Nield, that at future meetings the papers read should be of a nature similar to those which have already been brought before the Society.

A member suggested that a branch should be established in connection with the Society for the benefit of members in sickness or in needy circumstances. The idea seemed to find favour with the meeting, but it was decided that the subject should be brought forward for consideration next session. A vote of thanks to Mr. Swan concluded the proceedings.

CULTURE OF THE TUBEROSE.

THE Tuberose is not so well known, and consequently not so extensively cultivated in private gardens, as it deserves to be. This, too, is surprising, seeing that it is easily cultivated, and that its pure white and delightfully sweet flowers are so admirably adapted for bouquets and buttonholes during the summer, autumn, and early winter months; and to say that the individual blooms of the Tuberose—of which, roughly speaking, a spike contains two or three dozen—are nearly equal, if not quite, to Gardenias, which flowers they somewhat resemble, would be no exaggeration of their value. The Tuberose, like the *Eucharis*

amazonica, is very accommodating in its floral development, inasmuch as it only expands a few flowers at intervals of a few days at the bottom of the panicle, and so on, until the topmost flower is developed, and on this account a dozen plants in this stage of floral development would, for the purpose above indicated, yield a moderately good supply of flowers for four or five weeks at a time, every one of which, as they wire well, may be turned to good account. The cultural details are simple, but should be persistently attended to if success in flowering this sweetly scented plant is to be attained, and are briefly these. When the bulbs are being potted, which, in order to extend the flowering period, should be done at intervals of a fortnight from February to the middle or end of June, all the little bulblets and eyes should be rubbed off, and any suckers that may afterwards spring from the bulb be immediately removed, so as to concentrate the sap stored up in the bulbs to the production of flower spikes, otherwise failure to flower will, in all probability, be the result.

The Tuberose delights in a rich sandy loam with a sprinkling of leaf mould, and should be grown in 3-inch pots, burying three parts of the bulb, from which the old fibrous roots have been previously cut, in the soil. The pots should then be plunged to the rim in a Melon or Cucumber frame to start the tubers into growth, and subsequently the plants should be grown on near the glass to insure a sturdy growth. The soil should be kept rather dry until the flower stem appears, and when this is about 6 or 9 inches high, the plants being sufficiently moist at the roots, should be shifted into 6-inch pots, employing all loam. After this water should be withheld from the roots for a few days until they have taken to the new soil, and as the pots become filled with roots, diluted liquid manure should be given them, which will tend to the production and development of finer flowers. The plants should be syringed twice a day, if in a high temperature, to keep them free from the attacks of red spider, to which they are subject; but when the flowers begin to expand, syringing, which would cause the flowers to fade, should be discontinued, and the plants kept in an airy greenhouse or conservatory, where their perfume will be very agreeable.

The Pearl, a dwarf American variety from 2 to 3 feet high, and the African, from 5 to 6 feet high, are the best varieties to grow. Perhaps the individual flowers or pips of the last-named variety are larger and more double than those of the Pearl. The African variety is of recent introduction. The bulbs are much larger than the American ones. The only thing against the former variety in comparison with the latter is the fact of its requiring longer and stouter sticks to support the flower spikes. The foregoing remarks are made for the information and benefit of the uninitiated in Tuberose culture, and that if the instructions herein given are followed, and good bulbs obtained, success in flowering satisfactorily this charming plant will be their reward.—H. W. WARD.

“SOLIDIFIED SAP.”

WHEN I wrote last under the above heading it was not for sake of controversy, but in the hope of getting a clearer meaning of the term “stored up sap that has never solidified,” used by Mr. Iggulden (see page 43). What I understand stored-up sap to be is sap never really solid, but held in abeyance by cold or other natural causes, and flowing again when these are withdrawn; but to read it so in your correspondent's article leaves it meaningless. I look to Mr. Iggulden for a solution, which I have no doubt he is well able to give.—RITCHIE.

[Your correspondent will perhaps remember that I believe in the Grape Vine's capability of storing up a certain amount of food, but not in a liquid form, as he seems to imagine they do, or otherwise at pruning time—supposing I am right in the impression that the cells or sap vessels are connected—the liquid sap must drain out of the lower wounds. I used the expression “solidified sap” as being the simplest way of alluding to it without describing the process of the change in the character of the sap. The Vines under notice were not in a healthy state owing to defective root-action. No Vines in such a condition will ripen their wood or properly store food. If I had pruned those Vines referred to I know they would have bled freely; and this I hold would have been ruinous, as nothing coming from the roots subsequently would have compensated for the loss of that food which is so necessary for the formation of strong fruitful growths. Vines fairly well treated and with a good root-action contain no liquid food during the winter months, and if not solidified what has become of it?—W. IGGULDEN.]

NOTES ON POTATOES.—Having to grow Potatoes for a very large establishment, I take much interest in everything relating thereto, and Mr. Iggulden's observations under the above heading, page 183, were practical and important. Having often publicly given my estimate of the Champion, I am proud of the foremost position, as a general crop Potato up to March, that he gives it, but I dissent from having the drills or rows 40 inches asunder for it; larger tubers would be obtained, but

I and everyone I discussed the point with prefer smaller ones without a hollow centre. I intend to make my drills 32 inches apart. Another point in favour of the Champion is that it is the driest, and therefore a capital Potato for a dyspeptic or acid stomach.—W. J. MURPHY, *Clonmel*.

SOWING SEEDS.

THE above subject is a very important one to gardeners, yet the work is carelessly or indifferently attended to in far too many instances.

In the few remarks I offer for the benefit of your less experienced readers I shall endeavour to point out a few of the many causes of failures and how they may be remedied. To make my remarks more seasonable allusion will be made more particularly to annuals and such seeds as will be sown under glass during this and the next month.

The first requisite to success is procuring genuine seeds. Purchase the best to be had and from a reliable source, success or failure then rests very much with the cultivator. First as to failures—chief amongst these is sowing at the wrong time and in unsuitable soils. To illustrate better what I mean I will give an instance how such work is sometimes performed. It is to be hoped the practice is not general, but the writer has seen it more than once. It is this: Many annuals about the end of February or the beginning of March are sown indiscriminately. Numbers of different sorts of seeds are sown together, and this is a very bad practice. In the first place, it is a great waste of time and room when both are valuable; and secondly, with such free-growing annuals as Perillas, Tagetes, Tropæolums, and Zinnias, and others too numerous to mention, it is very detrimental to the plants to sow so soon. Again, seeds of Cucumbers, Melons, Vegetable Marrows, Tomatoes, and other quick-growing plants are frequently sown long before they are wanted, and in consequence occupy unnecessary space, to say nothing of the injurious effect it has upon their health by the check they receive through being root-bound. That failures will occur all know, indeed, the best practitioners are liable to them, but if a little common sense were used in the matter they might be much reduced.

The secret of success, if there is any secret in the matter, may be summed up in a few words. Sow always, if possible, at the right time and in properly prepared soils. To do this a thorough knowledge of the time the seeds to be sown will take to come to maturity is essential, as well as the time they are wanted at that stage.—JOSEPH RICHARDSON.

TOWN GARDENING VERSUS CHEMICAL VAPOURS.

GARDENERS who have practised all their lives in the pure atmosphere of the country are fortunate. They can form no conception of the perplexities and difficulties that others have to contend against in the neighbourhood of towns. The ordinary smoke of a town is not so destructive to vegetation as many people imagine. For instance, vegetation flourishes about London, even in the streets, better than in gardens four miles from Liverpool, and the same distance or a little more from the mouth of the river Mersey. It is not the ordinary smoke of the city that proves so detrimental to vegetation generally, but the chemical vapours that are carried to us with the north-westerly winds. I suppose it is the sulphuric acid from these chemical works that scorches and withers all with which it comes in contact. When large trees of Oak, Beech, Sycamore, Elm, and other forest trees, that have braved many a storm from the sea, but still grew and flourished, are now dying from the deadly influence of this destructive acid, we need hardly wonder at lowlier and less hardy forms of vegetation being cut, disfigured, and rendered unsightly.

Up to the middle of December I thought our lawns had never looked better, and congratulated myself upon their improved appearance through liberal top-dressings annually. But after one frost and a dense fog heavily charged with chemical vapours they had a scorched brown appearance as if burnt.

Although the weather up to the present has been remarkably mild, evergreens have suffered more in the gardens here than I have seen them in some of our severest winters when the temperature fell below zero. The storm experienced a few days after the dense fog alluded to carried with it salt spray from the sea. Rhododendrons (hybrid varieties) which endure exposure to cutting winds much better than *R. ponticum*, are much browned, and their leaves are falling. The latter exposed to the force of the gale are little better than bare sticks. Aucubas have suffered worse than I ever saw them after frost, and their foliage is as black as if each bush had had a fire beneath it. The Silver and the common green Holly in exposed places are completely stripped of their foliage, while the wood in many instances is already dead. The bold and hardy *I. Hodginsii* has suffered equally, some of the most exposed scarcely having a leaf upon them, the wood fast turning yellow, and will die. Shortly after this storm Holly leaves fell off in large numbers in this neighbourhood. The fog and storm combined caused this destruction, but the latter, I believe, did the greatest mischief. The glass of our conservatory and houses was thickly covered with salt, and had the appearance of shading just applied and caught with a shower before being dry.

This is disheartening to a gardener, but there is another side to this matter which is more perplexing still. These chemical vapours not only prove detrimental to vegetation outside, but when carried with a strong, or moderately strong wind, affect the inmates of our plant and fruit houses. This is more marked when fogs prevail at the same time. During the past two or three years we have generally experienced some of these fogs, and the wind in the direction for carrying these deadly

vapours when that now popular plant the Chrysanthemum has been developing its blooms. When plants have been grown, watched, and tended carefully for months, and then the flowers are cut and spoiled in a few hours or a day, it is most annoying. The Chrysanthemum has suffered much in this neighbourhood during the past few years in this way. Last autumn many flowers were destroyed and did not last many days after the fog cleared away. Zonal Pelargoniums (single varieties) suffer much; the flowers will fall in a shower, and after one or two fogs are useless. They do not suffer so badly from the fogs when the wind is not in a north-westerly direction. Crotons suffer, and none more so than that useful variety majesticus. I have had this throw off the whole of its foliage, while other varieties have not appeared to be affected, and on that account have had to discard it, except a plant or two.

The greatest attention in admitting air to all our glass houses is exercised when the wind is in the direction mentioned, but at times we are compelled to admit air, and have had the young tender foliage of Vines injured in consequence. I do not think we need wonder at the buds of Peach trees falling. They are falling here this year, and commenced about the same time as the Hollies, not only in the early house but throughout the range. Either chemical vapours or not lifting the trees is the cause; the former is the more likely. It is certain that annual lifting is a sure remedy against the buds falling. Our trees have been lifted annually for five years until last season.

Some years ago I was very anxious to be in the neighbourhood of a town, especially after practising in some quiet country district; but my advice to those in such places is, Be contented, for I wish this garden was in some rural district free from destructive chemical vapours where vegetation would grow and flourish.—W. BARDNEY.

POINSETTIA CULTURE.

REFERRING to Mr. C. H. Stephens' article on the above subject (page 60) I would like to discuss a few points in regard to his system of cultivating this fine autumn and winter-flowering plant. In the first instance I question if the plants should be removed to bottom heat as soon as they have flowered. Would not the cuttings come stronger by resting and ripening the wood? Secondly, why not insert the cuttings singly in thumb pots, so that they can when struck be shifted without a check? Thirdly, I cannot agree with Mr. Stephens by any means when he advises the plants to be housed in a temperature of 48° falling to 45°, for unless the greatest care be taken in watering they are sure to lose their bottom leaves. I do not consider heads 13 inches in diameter up to the standard, although by growing them as he advises I daresay that would be about the maximum size. Does he not consider the height of the plants of any importance? I think it comes next to size of head in point of excellence in their culture. Hoping your correspondent will pardon my criticism of his article, and kindly explain the details of his system of culture. I agree with the general substance of Mr. J. Saunderson's letter, which seems to proceed from a long-experienced cultivator of this plant. My object in penning the foregoing is simply to gain information.—A YOUNG READER.

MR. OWEN THOMAS.

As not a few of our readers will like to see what manner of man the newly appointed gardener to Chatsworth is, we have pleasure in publishing his portrait, which, we may add, is excellent and life-like. The selection of Mr. Thomas for the important charge on which he enters on Monday next, for which there were so many excellent applicants, indicates that he is a man of capacity—skilled as a gardener, well educated, and of becoming demeanour and address. Only a person possessing those qualities can fill satisfactorily such a responsible position in the gardening world as the subject of these notes will shortly occupy.

The professional career is not an eventful one. He has simply been trained in good gardens under good gardeners, and has made the best use of his opportunities. Born in a small village (Hermon) in Anglesea in 1843, he eventually commenced his gardening career at Bodorgan. He thus had the advantage of receiving his first lessons from Mr. Ewing, the inventor of glass walls, and who was well known to all readers of gardening journals twenty years ago as one of the most competent of British gardeners, and who, we are glad to say, is still hale and hearty, living in Chester in retirement on his well-merited success. Those who knew Bodorgan at that time (and they are many) need not be told that every branch of gardening was well and successfully represented there. Orchids that were not so common then as they are now, were especially fine, fruit both under glass and out of doors was excellent, and the rare collection of Coniferous trees planted with so much care and judgment now rank among the rarest and best to be found in the kingdom. Mr. Thomas was at Bodorgan about eight years.

In the spring of 1863 he was transferred by Messrs. F. & A. Dickson to the gardens of the Hon. C. Parker Jervoise, Aston Hall, near Sutton Coldfield, where he spent two years under Mr. Gardner, now and for many years gardener to Sir John Astley, Elsham Hall, Brigg, and to whom he states he shall always feel indebted for valuable practical lessons in gardening which have done him good service since, and also for his rare example in punctuality, straightforwardness, and gentlemanly conduct.

In the spring of 1865 he was sent by Messrs. Veitch of Chelsea as journeyman to Drayton Manor Gardens under Mr. Ballingall. In a little over twelve months he was offered the general foreman's place, which situation he filled for nearly four years. In the spring of 1869 he

left Drayton Manor for Messrs. Veitch's nursery with the object of obtaining a head gardener's place, and remained with them about eight months. At the end of that time he was sent for by Sir Robert Peel, Bart., to take temporary charge of the gardens at Drayton until a head gardener was appointed, Mr. Ballingall having left. In the course of a fortnight after Sir Robert and Lady Emily Peel offered him the head gardener's place without any solicitation on his part, which position he occupied with great satisfaction to his employers for thirteen years.

him the appointment as chief of the far-famed ducal gardens at Chatsworth. They will be in good keeping.

FURNISHING THE CONSERVATORY.

At the first glance this does not appear to be a subject on which much need be said. I, however, consider it is of much

Wm. Thomas

While at Drayton Manor, in addition to the full charge of the extensive and fine gardens there, he carried out many important improvements in the pleasure grounds, having oftentimes as many as fifty men under him. In July, 1882, he took charge of the beautiful gardens and grounds of John Corbett, Esq., M.P., at Impney near Droitwich, from whom he has received much encouragement and kindness, and who has expressed himself well pleased with his short service at Impney.

Such is the outline of Mr. Thomas's experience. His long term of seventeen years at Drayton, and his success in the management of the place and a large staff of men, has no doubt had due weight in securing

importance, and gardeners frequently lose sight of how their interests are involved in it. The gentleman engaged in the cares of business, and anxious under the risks which attend its operations, if he is the possessor of a conservatory, frequently turns to it for that calm enjoyment which is so grateful and which is often an antidote to those cares. Here, in the contemplation of its beautiful inmates, he may for a space forget the anxieties which have oppressed him. It may well be that the hope of this restful enjoyment has been the feeling which, more

than any other, has conduced to the erection of that structure; and it follows, then, if the conservatory from its unattractiveness fails to afford gratification, then it does not fulfil the purpose for which it has been built. This purpose is only half accomplished by furnishing cut flowers for the rooms of the dwelling house, or by enabling the proprietor to indulge in the pleasure of presenting an occasional basket of flowers to his friends. In the conservatory no unattractive plant should be suffered to have a place. If sickly it should be put where it can be nursed, with the view of bringing it again into a healthy condition. If its season of bloom is over it should be removed; and no plant whatever, unless pleasing through the profuseness or brilliance of its bloom, the richness, delicacy, or gracefulness of its flowers, elegance of growth, colour of foliage, or other qualification, should be allowed a place in that house. A few ornamental-foliage plants of a striking character and also Ferns, especially of the Maidenhair type, may be used with advantage; but it must be remembered that no quantity of the most brilliantly coloured or the most graceful foliage will compensate for an insufficiency of flowers, and that the chief attraction of the conservatory will always be in the flowers which it may contain.

In order to keep up a supply for the whole or even the greater portion of the year certain cultural rules must be observed. They may be varied slightly according to the circumstances of each place, but must not be entirely departed from. A regular and systematic course of operations in the preparation of plants is necessary. No haphazard cultivation, without any consideration as to the time of blooming, will succeed. It is true that as regards many of the summer groups their time of flowering is determined for us, and we can do little to advance or retard them; but there are other portions of the year during which it is more important the brightness of the conservatory should be maintained, and the plants for that purpose must be prepared with special reference to those times.

In endeavouring to carry out the requirements of cultivation, on which success depends, many difficulties will be encountered. Insufficiency of means in various ways—defective heating apparatus, unsuitable soils or houses, or perhaps both—and many rough-and-ready appliances will have to be used; and it is only by a close and intelligent attention and unflagging care that fair success can be obtained. But in the culture of greenhouse plants, as much perhaps as in anything, success depends on attention to details. Many hindrances, however, will present themselves which can be neither mitigated nor removed. The remedy for structural difficulties does not usually lie in the power of the gardener, and the obstacles which are met with in the cultivation of plants in pots are so numerous and varied that a correct estimate can be made only by those who have encountered them. There are, of course, many gardens where, from deficient accommodation and appliances, an abundant and continuous supply of flowers is impossible; and in places of moderate capacity where all or most of the houses are devoted to fruit culture it can be accomplished only to a limited extent. Where but a single structure exists, the character and appearance of a conservatory cannot be maintained in it. Plants are not in flower at all seasons of the year, and if no other places are provided for them they must remain where they have flowered after that period is over, unless they can be arranged out of doors. Two or three other houses should minister wholly or in part to the wants of the conservatory. Where, in addition to a Peach house or vinery there are a good greenhouse and pit, these, together with a frame or two, should be sufficient to furnish a fair quantity of flowers all the year round.

Let us enumerate some of the many plants available for this purpose. From the time when the spring bulbs begin to bloom until the end of September there is seldom any complaining of the lack of flowers. Spring, summer, and early autumn generally produce such an abundance of bloom both indoors and out, that all which need be done here is to glance at the chief groups of greenhouse plants in the order of their flowering. Following closely on the Hyacinths, Tulips, Deutzias, and Spiræas the Azaleas comprise the chief of the great groups on which we mainly depend; and where there is even a moderate collection of these the period during which they are at their best will probably be the gayest of the year. I need say little of these well-understood plants. The form which appears to me best adapted for general decorative purposes is the umbrella shape; but some, particularly of the double varieties, are better trained to some other form, as the blooms by reason of their weight lie in a position unfavourable for the eye seeing them advantageously. Young Azaleas in small pots are much benefited by placing the pot in which a plant is growing inside a larger one,

and filling the space between them with moss or some other suitable material. Their fine hair-like roots are thus kept more cool and moist. Many of the newer varieties far surpass some of the older forms in cultivation.

Long before the last of the Azaleas are out of bloom the earliest Pelargoniums will be claiming a place in the conservatory. We have in them a class of plants which for profuseness in flowering and telling combinations of brilliant colours have few equals; while the time during which they may be had in bloom extends at least over five months of the year. In an ordinary greenhouse the earliest varieties will commence flowering by the beginning of May, and at the end of September some of them will still be showing their richly coloured flowers. That their flowering may cover this long period it is necessary that certain treatment be given them. Most of the free-flowering sorts, if not checked after the first flowering, will flower twice in the same season. Such varieties as Digby Grand, Duchess of Bedford, and Bridal Bouquet will bloom freely a second time, a large proportion of the flowers coming from the axils on the old stems, so that in cutting off the dead blooms care should be taken not to cut too low down. The dwarf compact habit of many of the varieties in this section well adapts them for late blooming, as they need not be pruned so closely as the taller-growing sorts; and close pruning of Pelargoniums late in the year should always be avoided, or they will probably not break again, the energies of the plants at that time being nearly exhausted, and the season approaching when they should be in a state of rest. For late flowering, however, young plants from cuttings struck the previous autumn are the best. These, regularly tied down and pinched until the beginning of July, then placed in a cold frame or even in a sheltered position out of doors till the end of August, may be returned to the greenhouse to bloom, which they will continue to do far into the autumn. These late-flowering plants must not be pruned back like those which have bloomed earlier; they must not be entirely denuded of their foliage. Stopping any young shoot which may be too long is all that should be done. Neither must they be disrooted like the others, but allowed to remain undisturbed till spring.

With the Pelargoniums during June and July we have the herbaceous Calceolarias, which are deservedly popular for greenhouse and conservatory. As many of these as can be accommodated should always be grown, as few plants present a more beautiful and interesting appearance.

Of tuberous-rooted Begonias we have an extensive assortment, and their usefulness as decorative plants can scarcely be over-rated. Their floriferous character, beauty and variety of colour, and the gracefully pendant habit of their flowers have established them in popular esteem. From the beginning of June to the middle of October some of these plants will bloom continuously, and they are so accommodating in their habits that they are adapted for places of the smallest capacity. Dying down to the tubers, they may during winter be packed away anywhere secure from frost. When starting into growth the following spring, those which are not in pots sufficiently large, or whose shoots appear weak, should be repotted. Where they have enough root room, with good drainage, and are pushing strongly, repotting is not necessary; indeed, old tubers in large pots will grow and bloom well for several years in succession without being repotted. They must, however, have ample drainage. For the purpose of supplying cut flowers the section of which Begonia Sedeni may be taken as the type is better adapted than most of the others, although its flowers are not of the largest size. Begonias, however, are less valuable for cutting than for conservatory decoration.

Roses, although such general favourites, are not the best plants for producing a bank of bloom in the conservatory; and although that structure can scarcely be considered complete without the presence of the acknowledged queen of flowers, yet Roses, to be of much value there, should be of those varieties which will flower early and again in late summer or autumn. Most of the sections can be had generally so much better in shape, substance, and colour during early and midsummer when grown out of doors, that they will be much less esteemed in the conservatory during that period than they will be before and after it. When, however, the declining temperature and the dull, foggy, or rainy days of autumn render a good Rose out of doors a rarity, then a few Teas or Hybrid Perpetuals grown inside will be very welcome. One of the best Roses for the conservatory is La France. It does not produce a bloom from every shoot at the same time, but it will give a few of its splendid and deliciously scented flowers three times during its blooming season; and, unlike many other varieties, it does not

change or lose its colour under glass.—GEORGE WINTERBURN, *Weetwood Lane, Leeds.*

[The first-prize paper read at the Leeds Gardeners' meeting.]
(To be continued.)

CULTURE OF AZALEA INDICA.

THE varieties of *Azalea indica* are very useful and accommodating plants, and by having a good selection, a succession of bloom may be had from Christmas until the end of June. No plants are more effective either for house or conservatory decoration, and they are also well adapted for cutting. Large plants of the Fielder's and Chelsea Whites are valuable, and should be justly prized. I do not think there are two other Azaleas that will endure cutting like these excellent varieties, and by suitable treatment after blooming they will be as satisfactory as in the previous season. I will not recommend the propagating of Azaleas to amateurs and gardeners for various reasons. The principal one is, that useful decorative plants may be procured from any nurseryman who makes a speciality of Azaleas at a reasonable rate, and far more satisfactory than can be had by propagating them at home.

Failure with Azaleas is often due to improper treatment after they have flowered, especially if they have been forced. They are forced into bloom in a high temperature and a steaming atmosphere, and after blooming are placed in any corner of a cold draughty house. It is also a great mistake to overpot Azaleas. They should only receive small shifts, and then only if they require it. They should be potted very firmly, ramming the soil well round the ball. The soil should consist of good black peat and coarse sand, the pots being well drained. After Azaleas have flowered the seed pods should be picked off, repotting the plants if they require it; if not, give them two or three dressings of Standen's manure through the season, sprinkling it on the surface of the soil. Place them for the growing season in a warm moist house, syringe them well twice a day, and they will form abundance of bloom buds by the end of the season. They should then be hardened, and placed in the open air for two or three weeks in a sunny position, but sheltered from winds, subsequently transferring them to a light airy house. Plants after they have been forced should be placed in growing quarters directly after blooming. If care is taken on this point those that came into bloom first will form their flower buds early, when they will not require such hard forcing as those that set their buds late in the season.

Thrips are the greatest enemy to the Azalea, and should be destroyed by dipping small plants in a solution of nicotine soap. Large plants are more conveniently fumigated.—A. YOUNG.

ROYAL HORTICULTURAL SOCIETY.

MARCH 11TH.

PLANTS in flower were well represented at this meeting, the conservatory presenting a very bright aspect, groups of Cyclamens and hardy Primroses and Polyanthus being the leading features. The last-named were much admired, and their value at this time of year cannot be over-estimated, as either out of doors or in pots under glass they are very handsome.

FRUIT COMMITTEE.—Harry J. Veitch, Esq., in the chair. Present—Messrs. Phillip Crowley, J. Lee, J. E. Lane, G. T. Miles, William Paul, J. Burnett, G. Bunyard, S. Lyon, G. Goldsmith, A. Howcroft, J. Roberts, and Dr. Robert Hogg. Messrs. J. Veitch & Sons, Chelsea, were adjudged a bronze Banksian medal for sixty dishes of Apples in fine condition, fresh, firm, and of good colour. Especially noteworthy were Norfolk Beefing, Alfriston, Dumelow's Seedling, Annie Elizabeth, Lord Derby, Cooling's Favourite, Winter Peach, London Pippin, Duck's-bill, and Mère de Ménage. Mr. J. Burnett, The Gardens, Deepdene, Dorking, was accorded a vote of thanks for a collection of two dozen dishes of Apples, including some fine samples of Dumelow's Seedling, Norfolk Beefing, and Shepherd's Seedling. Both this and the preceding collection indicated how well Apples have kept this season, for some of them looked as fresh as if they had been only just gathered. Mr. R. Gilbert, Burghley Gardens, Stamford, sent several samples of a cross between Chou de Burghley and a Savoy, the latter being the male parent, and named Gilbert's Universal Savoy. They were of moderate size, very firm, and white; but the Committee expressed a desire to see it again, the specimens to be sent to Mr. Barron. Mr. Gilbert also sent samples of Bedfordshire Champion Onions, which were very fine and solid. Mr. Allan, The Gardens, Gunton Park, Norwich, sent fruits of a seedling Apple, which were considered to be inferior to many other varieties already in cultivation.

FLORAL COMMITTEE.—Section A.—G. F. Wilson, Esq., in the chair. Present—Messrs. T. Moore, J. Hudson, J. Fraser, H. Herbst, J. Woodbridge, H. Ballantine, J. Dominy, James O'Brien, Edwin Hill, J. Laing, Dr. M. T. Masters, and Rev. G. Henslow. Section B.—J. D. Llewelyn, Esq., in the chair. Present—Messrs. H. Eckford, H. Bennett, W. Bealby, J. Douglas, J. James, J. Child, G. Duffield, H. Turner, and H. Cannell.

Mr. A. Waterer, Knap Hill, Woking, showed two handsome specimen plants of *Andromeda japonica*, 4 feet high each and loaded with flowers, the long drooping panicles of white bell-shaped blooms being very attractive.

Several small plants were also shown to indicate their early-flowering character. Mr. Waterer was also awarded a silver Banksian medal for a group of 120 hardy Primroses and Polyanthus, comprising a great variety of colours, white, yellow, purple, mauve, lilac, deep red, and maroon. The plants were very healthy, and bore from six to twelve trusses of flowers. Some of them were certificated and are described below. Mr. J. James, Woodside, Farnham Royal, Slough, was awarded a silver Banksian medal for a large group of magnificent Cinerarias, the flower of astonishing size and richness of colours. It was indeed one of the finest groups Mr. James has ever shown, and proved not only the fine character of the strain, but also how well their culture is studied. Messrs. J. Veitch & Sons, Chelsea, had a pretty group of plants, *Staphylea colchica* being especially noteworthy, plants in 48-size pots, having twelve to eighteen spikes of white flowers each. *Primula obconica* was pretty, and several good Amaryllises were certificated. *Adiantum cuneatum* deflexum, a garden variety with small pinnules and graceful fronds, was represented by a strong plant, it is quite distinct and elegant. Messrs. H. Cannell & Sons, Swanley, had a handsome group of double Primulas, bright coloured Cinerarias, and the useful *Begonia Carrieri*, which was certificated. The Cinerarias were particularly fine, substance and size of flower being combined with neatness of form and clearness of tint. Mr. Cummins, gardener to A. H. Smee, Esq., The Grange, Wallington, exhibited a group of Orchids, the most prominent plant being a handsome specimen of *Lælia superbiens*, with seventeen pseudo-bulbs with three spikes 4 to 5 feet long and bearing ten flowers each. *Dendrobium luteolum* had three growths with from two to eight flowers each. *Saccolabium giganteum* illustre had two spikes of its white purple-spotted flowers. *Cœlogyne sparsa* is a curious and small-flowered species. The sepals and petals creamy white, the lip stained with brown; and *Cœlogyne Lemoniana* had six good spikes of flowers, the lip faintly tinged with pale yellow.

J. H. Mangles, Esq., Valewood, Haslemere, sent four superb trusses of *Rhododendron argenteum*, each with about twenty large white bells. A large plant of *Rhododendron grande* was also shown bearing several trusses of flowers. G. F. Wilson, Esq., Weybridge, sent a spike of *Odontoglossum Alexandræ* with fourteen fine flowers, some spikes of *Ada aurantiaca*. Mr. Ballantine, gardener to Baron Schroder, The Dell, Egham, showed a plant of *Odontoglossum Pescatorei Veitchii* with twenty-seven flowers, the blotches and bars of purple being extremely rich. Mr. J. Wiggins, gardener to W. Clay, Esq., Kingston, showed several good Primulas, Cinerarias, Cyclamens, several with fine flowers, and of good colour. Messrs. Paul & Son, Cheshunt, showed several new Amaryllises with large flowers, one being named General Gordon, but quite distinct from Messrs. Veitch's variety. A single Rose, named *Camellia japonica* was noteworthy, the flowers being suggestive of *Rosa rugosa* alba in size and shape. A silver Banksian medal was adjudged to Mr. H. B. Smith, Ealing Dean, for large groups of admirably grown Cyclamens, white, rose, purple, deep red, rich parti-coloured, the flowers of great size and numerous. A vote of thanks was accorded to Mr. G. Stevens, Putney, for plants of the bright *Abutilon Scarlet Gem*, which were flowering profusely. A bronze medal was awarded to Mr. J. Odell, Hillingdon, for a group of Queen Victoria Primulas, the flowers being of a very rich red colour, but not quite high enough above the foliage.

Messrs. J. Carter & Co., High Holborn, showed several hardy plants amongst them being *Saxifraga oppositifolia* major, with large flowers of a deep colour; *Saxifraga Sanctæ*, with bright yellow flowers; *Soldanella montana* in first-rate condition, flowering freely, and well deserving the cultural commendation awarded for it; *Iris reticulata*, *Bulbocodium vernum*; and the blue *Primula Scot Wilson* were also attractive. A vote of thanks was accorded to the collection. A vote of thanks was accorded to Mr. R. Dean, Ranelagh Road, Ealing, for a dozen plants of *Polyanthus Primroses*—General Gordon, crimson purple; Bridal Wreath, white; Novelty, lilac purple; Blue Beard, dark purple blue, very distinct; and White Queen, being the best of the varieties. A bronze Banksian medal was awarded to Messrs. Collins Bros., 39, Waterloo Road, S.E., for a fine group of *Anemone fulgens* flowers from Pau, and *A. fulgens* multipetala, and the Tenby Daffodil (*Narcissus obvallaris*), the bright yellow flowers being very attractive. Messrs. Barr & Son, King Street, Covent Garden, were awarded a bronze Banksian medal for a handsome collection of *Narcissus pallidus præcox*, which was awarded a first-class certificate at the last meeting, together with scarlet *Anemones* arranged with them for contrast.

First-class certificates were awarded for the following:—*Dendrobium Findleyanum giganteum* (Mr. C. J. Salter, gardener to J. Southgate, Esq., Selborne, Streatham).—A magnificent variety, differing only from the type in the great size of the flowers, which are over 3 inches in diameter, the lip nearly circular, 1½ inch across, and rich yellow in the centre.

Cattleya Trianae splendidissima (B. S. Williams).—A fine variety with white sepals and petals, and an intensely rich crimson lip and a yellow throat. It much resembled a variety of C. Mendeli, and if it had flowered a little later in the season would have well passed for one. It is, however, a superb Orchid, the colour of the lip being wonderfully rich.

Browallia Jamesoni (Cannell).—A charmingly graceful and striking plant, somewhat suggestive of a large *Rondeletia speciosa* in habit and form of flowers. The leaves are elliptical, 1½ inch long, the throat drooping and terminating in large clusters of tubular flowers with a bright orange limb nearly 1 inch in diameter.

Begonia Carrieri (Cannell).—Resembling a large-growing B. Schmidt, compact in habit, and bearing a great number of pure white flowers. A most useful winter-flowering plant either for cutting or general decoration.

Violet Wellsiana (Mr. Wells, Fern Hill, Windsor Forest).—A single variety. Flowers about an inch in diameter, deep purple and very fragrant. Plant strong in habit and free.

Polyanthus James Douglas (Waterer).—A fine variety; flowers flat, circular, pale yellow, with orange centre, 1½ inch in diameter, thirteen flowers in a head.

Polyanthus Prince of Wales (Waterer).—Flowers of wonderful size, 2 inches across, of a rich crimson colour, with a broad starry orange centre, eleven in a head.

Cyclamen Princess Ida (Edmonds).—A delicately pretty variety, with fine flowers, with broad petals of a soft pink colour. Very handsome.

Azalea indica Little Beauty (Veitch).—Very much like *A. amœna*, with rosy pink flowers 1½ inch across. The plant is of compact habit, and flowers very profusely. It was raised by Mr. Hovey of Boston, U.S.A.

Amaryllis General Graham (Veitch).—A grand variety, with very dark scarlet flowers 6 inches across, with broad petals.

Amaryllis Ne Plus Ultra (Veitch).—A superb variety, the flowers $7\frac{1}{2}$ inches across, bright scarlet, the petals $3\frac{1}{2}$ inches in diameter.

Rhododendron Princess Beatrice (Veitch).—Very distinct, the flower pale creamy buff with a tinge of rose, 2 inches across and about ten in a head.

Cineraria Royal Standard (James).—Flowers $2\frac{1}{2}$ inches across, rich crimson, of wonderful substance, the florets recurved and broad.

Cineraria Pollie Charming (James).—Flowers $2\frac{3}{4}$ inches broad, very symmetrical, the florets warm rosy crimson with a white ring at the base.

Cineraria Challenger (James).—Intense violet-blue in colour, very large; the florets thick and of great substance.

Rose Grace Darling (Bennett).—A pedigree seedling Rose of good form, the petals imbricated, of a bright pink colour and very fragrant.

Azalea Mrs. Heaver (Todman).—A double white variety, the flowers $1\frac{1}{2}$ inch in diameter, the petals rather pointed, but neat in form and full.

SCIENTIFIC COMMITTEE.—*Introduction of French Mushroom Spawn*.—A communication was read from Rev. M. J. Berkeley on this subject, brought before the Committee at the last meeting, in which he observed on the great uncertainty in the development of Agarics generally, the mycelium sometimes lying dormant for a year and then springing up vigorously. Agaricus arvensis and Marasmius oreades thus failed to grow at Chiswick; spawn from the Swan River likewise failed, the reason being that it is impossible to guard against minute differences of atmospheric and cosmical conditions, the failure being due to no fault of the cultivator.

Coryneum Beyerinckii.—Mr. Plowright sent twigs, with illustrations, with gummy exudations, proved by Prof. Oudemans to be due to the fungus in Holland.

Canker.—He also sent specimens caused by Nectria ditissima on Hawthorn. The canker on Apple appears to be of a different cause, which did not appear to be capable of discovery.

Pellia epiphylla.—Mr. G. Murray exhibited a specimen of this plant growing with moss and species of Jungermannia, on which it had acquired an abnormal habit of growing erect.

Knot in Red Currant.—Dr. Masters showed a specimen received from Mr. Webster of Gordon Castle. It was suggested that it was due to Phytophthora, which has been thought to cause the black knot in the Birch. Mr. MacLachlan questioned this hypothesis; Miss Ormerod appears to think it due to it.

Cones of Abies Fortunei.—He also exhibited cones and foliage of this remarkable Fir, which is intermediate between Abies and Picea. It was grown at Patlanza (Lago Maggiore), but is a native of China. The cork is remarkable as being exceedingly light, and apparently without the thin layers (Periderm) so conspicuous in Pinus maritima.

Servian Spruce.—He also showed specimens of the cones and foliage of this tree, figured and described in the *Gardener's Chronicle* for March 1st.

Phalenopsis Stuartiana.—Mr. O'Brien exhibited a specimen in which every petal had produced a small ridge down the centre, indicating in a small degree the protuberance on the labellum.

Hyacinths Grown in the Dark.—Mr. A. H. Smee exhibited specimens of purple and red Hyacinths, planted last October and sunk in pits, but covered by drain pipes and buried in cocoa-nut matting. The leaves were of a pale green, but the colour scarcely paler than usual, showing the independence of colour upon light.

Monstrosities.—He also showed a two-spined Anthurium; a Lælia anceps with anomalous petals, partly misplaced, and with none at all; a seedling Cyclamen with contorted and misplaced petals.

Apples Preserved in Dried Sand.—Sir J. D. Hooker exhibited Apples of two kinds, Duke of Devonshire and Court Pendu Plat, received from the Earl of Ducie. Professor Church remarked that he had preserved Apples for two years in charcoal.

Prevention of the Potato Disease.—A communication from Mr. Plowright on this subject was read, in which were detailed experiments showing the advantages of high moulding and in bending the stems to one side, though this latter process should not be done in the latter half of July, as it lessened the weight of the produce if done when in flower or at a time when the foliage was in full vigour. To prevent "after-sickness"—that is, impregnation of the tubers during or after being raised, they should not be dug up till a week after the foliage is quite dead. The paper concluded with a description of a method of disinfecting seed tubers by heating them at a temperature from 100° to 120° F., which killed all mycelium and spores, but left the germinating powers of the Potatoes uninjured. It is proposed to carry out experiments on Mr. Jensen's system at the Royal Horticultural Society's Gardens at Chiswick.

Plants Exhibited.—Mr. Loder brought the following which were referred to him for identification, many of them being unnamed, from the garden of the late Rev. Harpur Crewe:—Fritillaria sp., Galanthus virens, Tulipa altaica (?), the earliest species to flower; a Narcissus sp., Ornithogalum sp., forming dense mass of flowers 10 inches across, Narcissus obvallaris, Anemone patens, grown from seed from Colarado, Crocus versicolor, a curious nearly colourless Iris with semi-scarious petals, Fritillaria tenella, Narcissus citrina, and a green-sepalled Ophrys.

Tulipa Kaufmanni, sent by Mr. Elwes; a new species from Turkestan, with light crimson petals in one specimen, the three inner ones were white, but yellowish at the base. Epidendrum rhizophorum was sent by Hon. and Rev. J. T. Boscawen with particulars of its growth, a species requiring the very brightest sun; also Azara micropbylla from the same exhibitor.

LECTURE.—The Rev. George Henslow first called attention to a basket of magnificent Violets sent by Mr. Wells, Fern Hill, Windsor Forest. He remarked upon the general infertility of the Violet until the summer, when it bore numerous inconspicuous buds which never opened, but were very prolific. They would be readily found under the foliage. Primroses.—He next remarked on the fine display by Mr. Waterer and Mr. Dean, the former gaining two first-class certificates. The latter gentlemen brought the first example of a hose-in-hose Primrose, this peculiarity being hitherto only in the Polyanthus. It is due to the calyx being converted into a corolla. Cinerarias came in for some remarks, especially upon the enormous size of their blossoms, some of Mr. Cannell's being nearly $3\frac{1}{2}$ inches in diameter. Mr. Veitch sent three species of Pinguicula, which the lecturer took for remarks on the insectivorous habits of plants, and observed that although

such plants are peculiarly constructed for the purpose, yet in every seed when it germinates the same process of digestion is carried out to enable the embryo to grow at the expense of the food held in reserve. A Hyacinth grown in the dark by Mr. Smee had its blossoms of proper purple tint, this being due, not to direct light, but to the reserve material stored up in the bulb. This, of course, depends upon the foliage, and the green colour of the last only upon the light. The lecturer noticed that alpine plants, such as Soldanella and Saxifraga oppositifolia exhibited, as also the deep blue Gentians of the Alps, appear to become more intense in colour the higher they grow. M. Best proved the same thing to occur the higher the latitude, and thence deduced the result that the foliage is enhanced by the longer amount of sunshine; and this, then, indirectly enhances the flowers. He lastly called attention to a new variety of Narcissus sent by Mr. Barr called pallida præcox, of a pale lemon colour.

NOTES FROM A SCOTTISH GARDEN.

PARSLEY.—The time when we make our annual sowing of Parsley has arrived, and I make a note of the means we take to insure an all-the-year-round supply of this everyday herb. I say "annual sowing," for I find one sowing made at this time is sufficient to meet wants which cannot be called small; but when the sowing is made, the whole of our system of cultivation has not been stated. The sowing is only for the purpose of providing plants which in May are transplanted from the seed bed to the selected ground they are to occupy. A damp day is invariably chosen to plant out Parsley, setting them a foot apart. Highly cultivated ground is necessary. The plants are small when dibbled out, and do not receive water at any time. A sufficient number to yield a winter supply is at the same time put out where they can be protected by frames in that season. It is also a very good plan to grow a score of plants in pots in very hard weather, shifting them into 8-inch pots. The Parsley we grow is from home-saved seed, and does not extend over a foot across, the leaves being very finely cut and curled. Those who have merely sown Parsley in beds and left the plants without further attention would be surprised to find how extraordinary is the improvement when treated as above noted.

LILY OF THE VALLEY.—A correspondent several weeks ago declaimed against the practice of flowering Lily of the Valley earlier than March. I am unfortunate in having had it continuously since November, and am therefore not in a position to appreciate the good qualities of that most charming flower when first seen so late in the forcing season as March. However, as the flowers have been deliciously fragrant, accompanied with ample foliage, I am, perhaps, not so much to be pitied. What I want to note here is in the way of helping those who would like a supply of flowers either early in the year or at Christmas, for now is the time to begin preparations. Bought clumps in flower or prepared home-grown clumps in the same condition, instead of being turned out of doors when they have flowered, should be kept in a temperature of 55° to 60° in order to insure the formation of flower spikes and foliage for the ensuing season. As the year grows older and the general weather warmer less artificial heat is necessary, but the plants are not safe out of doors until all danger of frost is past. During summer, and indeed until the plants are wanted for forcing, they do well out of doors; plunged, however, to save watering. An ordinary stove temperature is high enough to bring the flowers and foliage out, only they must be kept in the dark until the spikes have grown considerably. Our home-grown plants are much superior to imported roots.

AURICULAS.—Increase is one great aim of most Auricula growers, and at present numerous offsets will be severed from the parent plants and placed on an independent footing. It ought to be generally known that a little heat does these offsets no harm, while the little plants are established and become strong much quicker through being kept in a temperature of about 50° . I have only once tried to accelerate the opening of Auricula flowers by a slightly higher temperature. The immediate object was gained, but the after results were such as to stop forcing for the future. It may be noted that Auriculas require more water during the next six weeks or two months than they do at any time during the rest of the year. Over-dryness is a frequent cause of failure with amateurs. One result of this is sometimes an extensive development of woolly aphides, a pest I have seen got rid of by planting out the stock.

WALLFLOWERS.—We have had a few delicious deep crimson Wallflowers all through the winter, and now the spring is bringing out the flowers in abundance. I do not think it is an extravagant statement to say that many young gardeners would be puzzled to know when to sow Wallflowers for an early spring supply. Practically, it is hardly grown in private gardens, yet few flowers give greater pleasure. In our northern climate I find March is a good time to sow the seed, transplanting during

summer into borders, where the plants grow into good-sized bushes and flower. A few plants are well worth lifting in autumn to be grown in pots; I hope to have some next winter in full bloom. The fine old double orange and crimson-black Wallflowers I have not seen for several years. I should be very pleased indeed to hear of them again.

THE EAST LOTHIAN STOCK.—This is another common flower well worthy a place in a greenhouse during the winter months. The month of March is quite early enough to sow for this purpose, and the plants should be grown in pots from the first, those 8 inches in diameter being large enough to flower them in. Plants grown in borders do not lift well. There are six varieties grown, those most suitable for pots being the white, purple, and a true crimson variety raised a few years ago. Some gardeners like the Wallflower-leaved forms. The variety sold as "scarlet" is hardly worth growing, the colour being an undecided shade of rosy lilac.—X.

PROPAGATING MISTLETOE.

SEVERAL correspondents have written for information as to the methods of propagating Mistletoe, and in compliance with their requests we republish the following notes upon the subject which appeared in the Journal some years since:—

The two principal modes by which Mistletoe is increased are by grafting

Fig. 46.

and seeds. The middle of May is the best time to graft the Mistletoe, and from then to midsummer. The best grafts are three-year-old shoots of the Apple tree, with a seedling Mistletoe on it already from the sowing of a thrush or blackbird, and the best way to graft it is to cut off all the leaves of the Apple-tree graft, and to leave at least four eyes, or buds, before the Mistletoe seedling, and only as much wood behind it as will be sufficient to make the union with the stock and no more; to have it done 5 feet high from the ground, to clay the graft in the usual way, to moss the clay, and to keep the moss damp, and to have the Mistletoe seedling just resting or nestling in the top of the ball of moss. Another most particular thing is to have one or more shoots left on the stock and above where it is grafted, and to let that shoot have all its leaves on. If the weather is very cold, or very hot, or windy, put a brown paper cape over the ball and Mistletoe, and nineteen out of a score of them ought to grow.

Grafting pieces of Mistletoe is like budding exactly, but make a longer and wider slit in the bark, and make the Mistletoe stem in a flat wedge-shape on one side, and put in the flat side next the wood of the stock, as in budding. Tie clay and moss, and cape with brown paper.

To bud Mistletoe is merely to take a less piece than the graft, only one joint of Mistletoe, "having a bud and one leaf at the end," but clay it and moss it, and paper-cape it as if it were a graft.

Now, in respect to sowing Mistletoe seeds in a slit made in the bark of the plant, or merely on the surface of the bark without the slit. Both ways are equally good, for it is not where the seed is placed that the Mistletoe seedling plant takes hold. A much more curious thing occurs at the germination of the seed of a Mistletoe. Sometimes there is only one germ in the Mistletoe seed; in others there are two, three, four, or more germs, and each germ throws up a sucker on the end of a short stalk. The sucker then lays hold of the bark of the tree, and holds on to it for six or eight, or more months, according to the time of the year; but it is from this sucker that roots penetrate the bark, and not from where the germination of the seed took place lower down. When there are more embryos than one in the one seed, there are as many seedlings from one seed as there are germs; for each germ, or embryo, has its own

branch and sucker, and each sucker takes an independent hold for itself, and on the place it holds to a seedling plant is established. I have seen three good plants thus from one seed, and each of them was half an inch in advance of the seed itself.

The seed of Mistletoe will vegetate on the bare handle of a house broom quite as readily as on the bark of an Apple-tree branch. If fastened with a bit of putty on a deal board, moss, and moisten it early in the summer, it will also vegetate on the board or on a bar of iron; then it dies, for the suckers at the end of the roots find not a proper place to fasten to.

The first indication of germination is the appearance of one or more radicles, like the sucker of a house fly, but larger; as at H I, which are front views, and at K L in the same figure, which are side views, taken from Mistletoe berries which were stuck on the upright trunk of a Cherry tree in March, and germinated there, as they appeared on the 20th May of the same year. When the white, viscous, pulpy matter of the Mistletoe berry is removed, the kernel or seed appears of a greenish colour, and flat; sometimes oval, or other times triangular, and at other times of various forms. A is the male blossom magnified; B, the female blossom magnified; D, a berry cut through transversely; E, a seed divided vertically, showing the two embryos; G, the embryo magnified; H, the two embryos, with the two radicles germinating; I, a single radicle; K, a side view, or section, of the two radicles; and L, a side view, or section, of the single radicle.

It is remarked by Du Hamel, that when the form of the seed is oval, generally one radicle only is protruded; but when it is triangular or irregular, two, three, or more appear. It is singular that, while the radicle of almost all other plants descends, this is not the case with the Mistletoe; the young root of which at first rises up, and then bends over till it reaches the body of the substance to which the seed has been attached, as at K and L. Having reached that substance, the point of the radicle swells out like the extremity of the sucker of a house fly, or according to the comparison of Du Hamel, like the mouth-piece of a hunting-horn.

GARDENS ABOUT BRISTOL.

HENBURY HILL.

THE garden connected with residence of E. A. George, Esq., has long been noted for the excellence of its various productions, Orchids in particular being at one time extensively grown; but the fine collection formed was a few years since broken up, and the houses are now filled with a miscellaneous collection of plants. The houses and kitchen garden, beyond which are the pleasure grounds and residence, are disposed near the brow of a rather abrupt southern declivity; and although the peculiar nature of the ground necessitates a rather peculiar arrangement of houses, the position would appear to favour good plant and fruit culture. Grapes, notably Black Hamburgh and Golden Champion, have long been well grown there. Both are grown on the extension system, and the latter confined to an inside border, and not hard-pruned, invariably perfects a heavy crop of fine bunches and but little spotted berries. The crop of Black Hamburgh was heavy and well finished, and other kinds of fruits are successfully cultivated.

The stove plants are principally such as are seen in the majority of good gardens in the neighbourhood, but the collection of Ferns includes one of the best specimens of *Adiantum farleyense* in the country. It is about 5 feet in diameter, is perfectly symmetrical, and the innumerable fronds are exceptionally large and healthy-looking. It is potted in good loamy soil, and when the roots fully occupy this liquid manure is occasionally given. Of the flowering plants the most noteworthy was the batch of handsome well-grown *Bouvardias*. They were planted out in a sunny sheltered position during the summer and early autumn months; and, being planted in fine soil in which leaf soil and sand abounded, they lifted readily with roots, a serious check thus being avoided. Such a batch of plants, placed during the winter months in an intermediate temperature, must prove of the greatest service, especially for furnishing cut blooms. A conservatory adjoins the residence, and this and the pleasure grounds were in perfect order.

Mr. Smith, the experienced gardener in charge, was the introducer of the extremely beautiful *Lavatera arborea variegata*, of which a good illustration was given in the *Journal of Horticulture*, June 7th, 1881. Mr. Smith does not consider it perfectly hardy; in fact it is best to lift a part or the whole of the stock of plants in the autumn and use them for the decoration of the conservatory and greenhouses during the winter. The seed of it, in common with other Mallows, germinates freely, and the variegation becomes more pronounced as the plants gain strength. The value of tuberous-rooted *Begonias* for summer bedding purposes has long been recognised by Mr. Smith, and he has succeeded in perfecting a strain superior, probably, to any in the hands of any other private grower. At any rate, I have not before seen such beautiful beds of *Begonias* in any private garden. The plants are very sturdy and even in growth, and were crowded with large well-formed flowers, at a time, too, when Zonal *Pelargoniums* were looking very shabby indeed. One bed was thinly filled with the *Begonias*, a groundwork being formed with *Mesembryanthemum cordifolium variegatum*, and this lovely mixture is to be commended both for effect and also for economy when *Begonias* may be scarce. It must be remembered that a poor dry soil, such as Zonal *Pelargoniums* will frequently succeed in, will not grow *Begonias* satisfactorily. They require a well-worked soil to which leaf soil or decomposed manure has been freely added. At Henbury Hill there is a remarkable collection of hardy Ferns as well as alpine plants, and these are most

picturesquely arranged, the peculiar habits of each species being studied in the arrangement. Another striking and very uncommon feature is a high wall exposed to the south entirely, and heavily covered with *Ceanothus azureus*. This always neat and ornamental drapery when in bloom can be seen at a great distance, and is the cause of much speculation to many passing horticulturists.—W. IGGULDEN.

KITCHEN GARDEN.

Spring Onions.—The main crop of these should be sown as soon as possible. The soil for their reception must be deeply dug and well manured. Sowing should only be done when the surface is dry and in good working order. Do not form beds, but sow in rows, which should be 1 foot apart and $1\frac{1}{2}$ inch deep. The seed should be sown thinly, and it is an advantage to cover it with a little sand or fine dry soil, then put on what was drawn out of the drills and tread firmly. When the surface is dry enough roll the whole piece, as nothing tends so much to produce finely shaped, small-necked bulbs as a firm soil. Of varieties the best to sow at present are Webb's Banbury, Sutton's Reading, Bedfordshire Champion, and James's Keeping. The two former attain a handsome size; the two latter, especially the last, are excellent keepers.

Parasnips.—The sowing of these should be finished at once. Where the soil is very shallow, and the long ones fork as a rule, sow the Turnip-rooted variety. It is very like a Turnip in shape, and is useful.

Peas.—Plants produced from seed sown under glass, and which are now being hardened under frames, should be transferred to their bearing quarters. In a favourable situation, and with care in hardening and planting, such crops may be had earlier than in any other way, but the utmost care is required to prevent their being checked. The roots must not be disturbed to any extent, and some dry soil from the sheds should be placed against them in planting. Stake at once and protect from cutting winds. Earth-up and stake Peas sown in the open some time ago. Marrows and main crop varieties generally may now be sown. Give them plenty of room and a rich soil. Of extra good varieties for sowing now we may name Carter's three splendid sorts—Telephone, Stratagem, and Pride of the Market; Duke of Albany, a new one of great merit; Telegraph, Giant Marrow, Champion of England, and Webb's Electric Light.

Broad Beans.—More of these may be sown. Aquadulce is a capital summer sort. Last year we had pods of it 16 inches long, and it is prolific and good. Do not sow this crop in the best part of the garden, as situation is not so important as a rich firm soil.

Celery.—Young plants must have plenty of light and air on all favourable occasions. Seed may be germinated in heat, but plants should be reared in ordinary frames. Those ready for transplanting should be placed into a frame with a gentle hotbed at the bottom and a rich soil over it, in which to dibble them. When not available we have substituted boxes for frames with good results. Sow a pinch of seed in gentle heat. Old Celery is now nearly over; clear the ground and prepare it for other crops.

Spinach.—Make a sowing of the round variety fortnightly now in large or small quantities, according to demand. We never give it a foremost place, but obtain all we require from between Raspberries, Gooseberries, and other crops.

Cauliflower, Savoy, Brussels Sprout, and Cabbage seed may be sown in quantity on a border to supply stock for transplanting in May. Lettuce may also be sown. Proceed with planting second early Potatoes. Keep the seed tubers of later varieties well spread out and exposed to the light. Make a new plantation of Horseradish; strong straight pieces should be dibbled into the ground in rows 3 feet apart and 1 foot from plant to plant. Seakale may be treated in the same way. Good soil should be provided for both. Where plantations of Seakale have become very old take up all the old stumps and only plant the crowns, cut off singly with a few inches of stem attached to each. All unoccupied ground should be manured and dug ready for cropping by this time. There will be much sowing and planting shortly.

FRUIT FORCING.

FIGS.—Early Trees in Pots.—The fruit having completed its first swelling, the most important matter is to pay strict daily attention to watering with diluted liquid manure a few degrees warmer than the house of which, if the pots are duly drained, the Fig at this stage will take great quantities without injury, but if they are allowed to want water—it may be but once—it is likely all the most forward fruit will fall just when they should be taking their last swelling. If the roots have passed through the top-dressing they may, if carrying a heavy crop, have large pieces of turf laid over the tops of the pots and extending to the bed of fermenting materials, into which they will root, and being fed judiciously the fruit will be much improved in size and quality. The day and night temperature need not be increased until the fruit begins to move, when a slight increase may be given, but in the meantime the foliage must be well syringed in the morning and afternoon of fine days,

damping the floors and walls, and close sufficiently early for the heat to rise to 80°. Great care must be given to the ventilation, particularly in bright weather succeeding a dull period, when early ventilation will be necessary in order that the tender young foliage may escape scorching. Keep a sharp look-out for red spider, and apply the usual remedies promptly. Pot young plants as soon as they require it, not allowing them to become much root-bound before doing so. Grow them in moist heat, and train to single stems.

SUCCESSION HOUSES.—Trees planted out will require regulating, tying as the growths proceed. Stop all side shoots at the fifth or sixth leaf, and lay in terminal shoots at full length until they have filled the allotted space. Syringe well twice a day, and damp all paths and borders at closing time; mulch and water the borders so as to encourage a sturdy growth, which is the most effectual means of keeping red spider in check.

PINES.—The winter season often makes the foliage of these plants somewhat tender and susceptible to injury from sudden outbursts of powerful sun, which are not infrequent at this time of year, hence great watchfulness must be exercised in the ventilation until the leaves become inured to the more powerful effects of the increased sunshine. Prompt attention must be given early in the morning to admitting a little air at the top of the houses, so as to dissipate the moisture before the sun is powerful. If the potting alluded to in our last calendar under this head be not already effected it must be attended to without delay. Attention must be given to the fermenting beds, because the heat rises very rapidly in them at this season, and the new young roots are soon injured by having too much heat. All plants should be examined at least once a week for watering, giving them thorough supplies of tepid liquid manure whenever they require it. Let the necessary attention be given to fruiting plants with superfluous suckers by screwing off the hearts of such as are not wanted, and afford to fruiting plants an abundance of moisture when the house is closed, in order to counteract the drying influence of artificial heat. Beds heated by hot-water pipes and shallow in depth sometimes become very dry, when a suitable occasion should be taken advantage of to give the plants and bed a good soaking with tepid water, which will produce a highly beneficial condition about the plants by increasing the supply of moisture.

Strawberries in Pots.—The plants are now pushing vigorously, but the earliest batches from the imperfect ripening of last autumn have thrown up leaves in advance of the flower trusses, the only remedy for which is a moderately warm temperature with a free admission of air. With the increase of light and heat the progress of succession plants will require attention so as to insure a steady supply. This is easily effected where Strawberries are grown in forced fruit houses in different stages or times of starting, and with a house specially devoted to swelling off the fruit there need not be any break in the succession, provided due regard be had to the difference of varieties with regard to the time of ripening. The blank most commonly occurs between early forced crops and later ones, if it should happen that a late variety succeeds an early one. Some endure forcing well and ripen quickly, as Vicomtesse Hericart de Thury, and La Grosse Sucrée, but other varieties must be brought on slowly, standing forcing after the fruit is set, but up to that stage make slow progress. If such varieties as Dr. Hogg, British Queen, Sir Charles Napier, and Cockscorn are to succeed early sorts, allowance must be made accordingly. These varieties, which are admirable for late work, should be brought on slowly in a good position near the glass, with plenty of air and abundance of water at the roots. The aphides generally appear with the flower trusses. These must be thoroughly disposed of by fumigation before the flowers open. Plants swelling off their fruit should have good supplies of tepid liquid manure two or three times a week, according to the condition of the plants and crop, and the plants should be looked over for water twice a day, and in very bright weather three times, as nothing hinders the swelling or encourages red spider so much as a deficiency of water at the roots.

PLANT HOUSES.

Shading.—The majority of the occupants of the stove that required potting will have been attended to by this time; and if the blinds are not already fixed upon the house, it should be done without further delay. The sun has now considerable power, and when shining in full force upon such plants as Marantas, Eucharis, Anthuriums, and others that have had the whole of the old soil removed from amongst their roots, will prove injurious. If not shaded their foliage will flag, and this, as far as possible, should be prevented if the plants are to commence root-action and establish themselves early. No air should be admitted through the ventilators into this structure until the plants are rooting freely. A close moist atmosphere and protection from the strong rays of the sun are the conditions under which the plants will rapidly become established and start into growth. The blinds should not be injudiciously applied, or the plants will grow weakly, and as the season advances they will be tender and incapable of bearing strong light.

The south side of the conservatory or any structure kept bright with flowering plants should also be provided with blinds, and in readiness for drawing down at any time when the sun is bright for an hour or two. Plants in full flower do not last in good condition nearly so long when the sun is allowed to shine with force upon them, neither do the flowers retain that freshness and brightness of colour which is so desirable. It is too early to apply permanent shading, and sooner than do this shading altogether for some time should be dispensed with.

The Orchid houses should be supplied with their blinds in readiness for the time when they are required. The blinds may now be drawn down daily on the south side of the Odontoglossum or cool house when the sun is bright, but on the other houses the shading need not be applied

for a week or two longer except where the *Phalænopses* are grown. When there is a good circulation of air in the cool house the atmosphere and the surroundings of the plants dry too quickly, under which conditions they will not thrive so well as when a cool uniform temperature can be maintained. The use of the blinds is the only means by which this can be accomplished.

THE BEE-KEEPER.

ABOUT LIGURIAN BEES.

LAST week I promised to adduce evidence in corroboration of my opinions on the value of Ligurian bees. I took advantage of a rather extended intimacy with bee-keepers to ascertain how others had fared, and was much surprised to find how completely my own opinion was borne out. I should mention that I only took into account those who had from three to five years' experience at least with Ligurians, as I consider it takes that time to find out all their failings. I need not dwell at great length on the result of my inquiries. One says, "We never knew what foul brood was here till a lady got some Ligurians from London, and it is quite a pest now." Another writes, "I have never had any satisfaction with my bees since I gave up keeping the old sort." A third says, "A friend and myself paid £8 for two stocks of Ligurians some years ago, and we have both spent many pounds on them since, but they never did us any good, and neither my friend nor myself would now take them as a gift;" and so on through the whole of my correspondence. I only had two out of about twenty replies to my inquiries who had a word to say in their favour. One of these "liked them because they were so pretty," and the other because they were so easily handled by ladies; neither, however, had ever obtained much surplus honey from them.

Of course, most of the opinions obtained were those of the ordinary run of bee-keepers, but I must give prominence to what I learned from two well-known apiarists whose judgment is of the utmost value in deciding the question. The first is a bee-keeper who dealt in Ligurians for some years, and stood by them as long as he could. At a personal interview, and in response to my inquiry, he told me "he found Ligurians so delicate there was no doing any good with them, and the longer he kept them the worse they got. The second is a gentleman who wrote favourably of Ligurians a few years ago both in the British and American journals. He is well known and highly esteemed as an authority on all matters pertaining to bee culture, and this is what he characteristically says now—"Italians are useless with me, they store no surplus, and are a nuisance as robbers and plunderers. I shall root out every skin of them from my apiary before the year is out."

Surely there is enough here to convince the most sceptical that something is radically wrong about these bees, that they are not suited to our climate, and, whatever they may do elsewhere, they fail here. Now if this is so, what can be more fatal to bee-keeping as a pursuit, both as it concerns bee-dealers and honey-producers, than to continue to perpetuate a constant source of mischief in pushing the sale of Ligurian bees? I have some valued friends in the trade who will, I hope, acquit me of any desire to injure their business; nevertheless, I confidently assert that they are doing harm to themselves as well as their customers by sending out bees which can only bring discredit on the vendors who recommend them. If it were not for the fact of bee-dealers being as a rule non-producers of honey, the failure of Ligurians as honey-gatherers would be as patent to them as it is to such of us as have tried them for honey only.

In conclusion, I would urge one or more of our prominent dealers to cast aside the reluctance to acknowledge the failure of Ligurians which seems to prevail among the trade, and cease selling foreign bees altogether. Let the plain truth be told about them, it's bound to come out before long; and if a good strain of the old black sort is cultivated, none but good queens being sent out, I venture to predict for the sellers an increased trade, yielding more satisfactory results to all concerned, while we shall inaugurate a new era in apiculture which will replace the present discouragement, largely attributable, I make bold to say, to the introduction of Ligurian bees.—W. B. C., *Higher Bebington, Cheshire*.

THE article from the pen of "W. B. C." on page 197 is precisely what I have been longing to see, but feared I never should. Anything that can stop the inundations of Ligurian queens is to be welcomed, but such a straightforward matter-of-fact "clincher" is beyond all price. The facts are what are wanted, and there they are. I hope everyone who does not want to see the blacks extinguished will do his utmost to prevent their extermination, which must be my excuse for troubling you with this.—H. V. EDWARDS.

TRADE CATALOGUES RECEIVED.

Samuel Shepperton, Prospect House, Belper.—*List of Florists' Flowers*.
Henry Bennett, Pedigree Rose Nursery, Shepperton, Middlesex.—*List of Pedigree Seedling Roses*.
R. B. Laird & Sons, 17, South Frederick Street, Edinburgh.—*List of Florists' Flowers*.
W. Hean, Quick & Co., Barnstaple.—*Catalogue of Clovers, Grasses, and Farm Seeds*.
Vilmorin-Andrieux & Cie, 4, Quai de la Mégisserie, Paris.—*Catalogue of Trees, Shrubs, and Palms*.

TO CORRESPONDENTS

* * All correspondence should be directed either to "THE EDITOR" or to "THE PUBLISHER." Letters addressed to Dr. Hogg or members of the staff often remain unopened unavoidably. We request that no one will write privately to any of our correspondents, as doing so subjects them to unjustifiable trouble and expense.

Correspondents should not mix up on the same sheet questions relating to Gardening and those on Bee subjects, and should never send more than two or three questions at once. All articles intended for insertion should be written on one side of the paper only. We cannot reply to questions through the post, and we do not undertake to return rejected communications.

Books (F. J. E.).—As an introductory work on chemistry you will find Roscoe's "Elementary Chemistry" (Macmillan & Co.), a useful work, and for more advanced study Johnston & Cameron's "Elements of Agricultural Chemistry and Geology" (W. Blackwood & Sons), is the most suitable. The "Handbook of British Plants," published at this office, price 3s. 6d., post free 3s. 8d., will enable you to determine wild flowers. The manual on the greenhouse, published at this office, price 9d., post free 10d., is the cheapest on the subject; the other work you name is also a good one. (*H. O., Bradford*).—The best works on Roses are those by Mr. W. Paul—namely, "The Rose Garden," 21s.; without plates, 10s. 6d. "Roses in Pots," 2s.; and "Roses and Rose Culture," 1s. (Kent & Co.), which gives all particulars respecting Roses indoors and out. "The Garden Manual," published at this office, price 1s. 6d., post free 1s. 9d., contains practical details of general garden work, and "The Greenhouse," price 9d., post free 10d., also at this office, deals with the culture of cool-house plants.

Seedling Conifers (E. P. C. B.).—The parcel has only just reached us as we are preparing for press. All the examples are good, some of them of marked excellence. For exhibiting we think they could be arranged and examined to greater advantage in boxes than planted out. If established in boxes they should be placed in them at once, and of course will need attention throughout the season. You would do well, however, to obtain the advice of the secretary on the details of exhibiting. The Asparagus seedlings are fairly good.

Hippeastrum reticulatum (Constant Subscriber).—Your plant is not a Lily, but an Amaryllis, and one of the most useful of the family, as, whether in bloom or not, it is attractive, its foliage alone rendering it an acquisition amongst stove plants. By repotting at once in good rough turfy peat and loam in equal proportions, adding a little charcoal, and growing the plants in a moist atmosphere till the end of August, and then withholding water so as to cause the foliage to shrivel a little, but not to turn yellow, they will bloom freely about October. The flowers are very handsome, and are sweet-scented. Do not overpot, but press the soil rather firmly and give abundance of drainage.

Leaf Soil (R. H. R.).—The decayed vegetable matter, of which you have sent a sample, as taken from a ditch, will be useful for mixing with heavy loam for general potting purposes, or at least that portion taken from near the top, as that taken from the bottom of the ditch may probably be sour. No portion of the sample sent is nearly fibrous enough for Orchids. Mixed to the extent of from one-third to one-half with loam that does not contain lime, adding also sand liberally, you would have a good compost for Camellias. The exact quantity of the leaf mould to use can only be determined by the character of the loam. It is much too light to be used alone for Camellias. It would be excellent for spreading in the drills when planting early Potatoes in heavy soil.

Wheat (J. M.).—Both the samples sent are of Wheat, No. 1 being inferior, No. 2 fairly good.

Cooking Potatoes (G. S.).—There is no wonder you have complaints of Potatoes being watery that are peeled at night and allowed to remain in water till the next day and then cooked, and we cannot understand how persons who enjoy good Potatoes should allow such an utterly unsound method of preparing them to continue.

Plants in Vineries (Idem).—Vineries can be rendered attractive by plants when suitable kinds are employed that endure shade in the summer; but to expect a house devoted to the culture of Lady Downe's Grapes to be kept as "gay as a conservatory all the year round without impairing the keeping properties of the Grapes" is unreasonable. At the same time there is no necessity for the Grapes to hang on the Vines "till March," as they can be cut in January and kept with their stems inserted in bottles of water in a

cool room. After Vines are pruned a house may be kept quite gay with bulbs in pots, Cinerarias, and a number of winter and spring flowers.

Primulas and Cinerarias (W. H.).—The Primulas are bright in colour, but there are many similarly bright in cultivation. The strain, however, is well worth preserving, and will eventually, perhaps, afford larger flowers. The Cinerarias are very inferior as compared with the best English-raised flowers.

Rabbits in Garden (A. E. T. T.).—Since dressing the plants and borders with soot fails to keep off the Rabbits, we regret that we are not acquainted with anything used in the same manner that will have the desired effect, but if any of our readers can name anything they may have found effectual we will readily publish it. With wire netting properly fixed and kept in order rabbits can be excluded from gardens.

Tobacco for Fumigating (W. C.).—Ordinary cut tobacco—that known as “shag,” is very good for this purpose; but much of the tobacco refuse sold is practically worthless, as it will not burn freely. Far more useful and economical is good tobacco paper. This varies in quality, also in price. If you procure a kind that does not suit you exactly, try some from another maker. In not a few cases when failure occurs it is more the fault of the operator than the material in his allowing insects to become so numerous that they can only be destroyed by fumigating so strongly as to injure the plants; but we do not suggest or think that you are one of those who err so seriously. The safest plan is to fumigate lightly to prevent the increase of insects, and it is also more economical than any other.

Cucumbers Dying (T. W.).—The fact that the Spiræas went off in the same manner as the Cucumbers would appear to indicate that the unfortunate result is due to fumigation or to something that has been used in the house for the extirpation of insects. The most strange part of the matter, however, is that your gardener cannot account for the collapse of the plants. Provided the pipes supply the requisite heat, then furring, if any, would have no such pernicious effect; and it is not conceivable that any gardener would allow such sharp currents of air nor such a degree of dryness in the house or the soil as to cause the destruction of the plants. Has he been the victim of circumstances over which he has no control?

Mushrooms in a Shed (Willing to Learn).—The shed will be well adapted for a Mushroom bed, provided you can maintain a temperature of 50° to 55° under the straw that you use as a covering; and this you may easily do by the time the manure is ready, if the bed is not too small. It should be 6 feet long and, if flat, 4 feet wide. If in the form of a ridge let this be 3 feet wide at the base and 3 feet high. There is no better place for preparing the manure than an open shed. The rather strong soil from under the surface of a pasture will be suitable. If you follow the instructions in the work intelligently you will succeed in your object, as many others have succeeded with no such means as you have at command.

Mixture for Shading Conservatory (Idem).—There are two distinct methods of shading—namely, portable in the form of roller blinds; and permanent by applying a mixture to the glass. We prefer the former, but the latter answers very well for large houses and various plants, such as Ferns, Palms, and Camellias. For flowering plants we employ light canvas blinds, and only use them when the sun is bright. The best mode of affixing the blind is undoubtedly, in our opinion, on a light iron framework a foot above the glass. The plants do not become “drawn” under such a shade nearly to the same extent as when the material rests on the roof; still with attention and judgment the latter plan answers very well. A very good wash for applying to the glass is made as follows:—Ingredients: 1 lb. of wheat flour, half pound of whiting, and 1 lb. of common candle or Russian tallow. Make the flour into a paste, and then put in the candles while the paste is hot, crush the whiting into a powder, mix with cold water, and then add to the paste, also adding as much Brunswick green as you need. When required for use warm it in a pail and paint the glass when the sun is shining upon it.

Fowls Trespassing (A Weekly Reader).—It is the duty of your neighbour who keeps fowls to “wire his garden off” to prevent them trespassing, and he can be compelled to do so, or adopt some other means of keeping them at home, unless he prefers paying for the damage they do. For this he is liable and actionable through the County Court. It is not incumbent on you to erect a barrier. You must not injure the fowls in any way, or you will be actionable. Give your neighbour a written notice that any damage his fowls do in your garden will be estimated by a competent gardener, such as the value of the crops that may be lost or depreciated, and for the amount so determined you will sue him through the County Court. On the claim being proved a just one it will be allowed, with any costs you may incur in connection with the case. That is your remedy.

Preserving Pollen of Aucubas (S. M. W.).—Several methods of preserving pollen have been successfully adopted, but the principal point is to keep it dry and cool. It should be carefully removed from the anthers and exposed for an hour or so, but not in the sun, and it can then be placed in a dry glass phial, which must be closely corked and kept in a cool position. Some have advocated placing the pollen upon the concave side of a watch glass, and on this another glass, the edges being secured with gum. If the plants are in pits they can be had in flower about the same time by placing one in moderate heat and the other in a cold shaded position.

Cattleya Trianae Variety (W. H., Leeds).—There are many light-coloured varieties of Cattleya Trianae, such as *delicata* and *nivea*, the latter being white and somewhat resembling your flower; we do not, however, remember one in which the lip is so white as in that you sent, as there is usually a tinge of colour in the centre. By all means preserve the plant, as it will afford a pretty contrast with the ordinary dark forms.

Growing and Preparing Tobacco for Fumigating (Cambridge).—The best kind for fumigating purposes is the common Tobacco plant, *Nicotiana tabacum virginicum*. *N. macrophylla gigantea*, *N. grandiflora purpurea*, *N. wigandoides*, and the variegated-leaved, are fine foliage plants for sub-tropical gardening, but we do not know what value they may possess for fumigating. The seeds should be sown in pots or pans of light rich soil early in April, placed in a hotbed, and the plants grown in gentle heat, having

them near the glass to keep them sturdy. Prick off the seedlings in pans or boxes, keeping them rather close and shaded until established, when they should be gradually hardened-off preparatory to planting out at the end of May. The plants require rich soil, and should be grown in rows about a yard apart, and a similar distance in the rows. During the period of growth the ground must be kept well hoed and stirred. As soon as the flowers begin to show colour break off the head of the plant and the small top leaves. This will induce in a short time the production of side shoots, which must be removed as soon as they appear, and the whole vigour of the plant will be directed towards the leaves. The leaves are to be gathered as they become yellow, tied together in small bunches, and hung up in some shady airy place to dry. After they have become thoroughly dried and crisp watch the first opportunity of a humid state of the atmosphere, which will cause them to become soft, and then pack them even in a box with the butts all one way, press them moderately, and a slight fermentation will shortly take place. All that is necessary is that a slight warmth be generated, then open it all, shake the bunches in the air to let off the heat, and repack it lightly. When all appearance of fermentation is over it may be stored as tightly as possible in a barrel and kept for use.

Raising Vines from Layers (H. S.).—In layering the cane of the Vine into pots to raise young canes from the eyes it is necessary to have the pots on a somewhat lower level than that of the base of the cane, otherwise the topmost eyes will break strongly and form strong canes, whilst those at the base will be weak, if, indeed, they break at all. We should rub off all the eyes not wished propagated, and one or two at the base to continue the growth of the parent plant, and when these have broken select the best, rubbing off the other. When the layered eyes have rooted well they should be detached from the parent, so that the latter may not be impoverished, as the strong growth in the layers is only had at the expense of the parent; which, if we understand you correctly, is wished to make a vigorous growth this season and become a permanent Vine. Remove the eyes of those you do require to layer with the point of a knife. The cause of the Vines from eyes growing so weakly is probably due to their not being grown in heat or not having liberal treatment, as it is no uncommon circumstance to grow Vines from eyes in a season as thick as a finger, and to carry 6 or 8 lbs. of ripe Grapes within eighteen months of inserting the eyes.

Heating Detached Vineries from One Boiler (A Novice).—There is no reason why you should not heat the whole of the four vineries from one boiler, provided the boiler can be fixed low enough to admit of the pipes connecting the detached vineries being taken under ground. The vineries are no doubt planted with different varieties of Grape Vines, so as to come in at different seasons; but you do not state this, and the proposed line or direction of pipes indicate your using the whole of the piping at once, having a similar heat in all, which would lead to the conclusion that the crops are wanted to come in simultaneously. Besides, if you have the “lean-to vinery at the south gable-end of dwelling” employed as an early house, and make use of the span-roof vinery as a late or even midseason house, you will have heat in the early house when it is not wanted, by being obliged to heat the water in the early house to obtain the requisite temperature in the span-roof house, the pipes in the latter being only extensions of those in the early house. Now, unless you want the whole of the houses heated at the same time the proposed mode of heating will not answer. The apparatus ought to be so contrived that each house can be heated separately or together, and that can readily be done by taking direct and separate flow and return pipes from the boiler to each house. The connecting pipes should be taken in a flue, and should be placed clear of the bottom, sides, and cover, so as to lose as little heat as possible; and it would be a still further advantage if they were covered with hair felting, so as to prevent the radiation of the heat from the pipes into the flue. The pipes may be taken through the houses as shown in your sketch, either in covered flues or covered with hairfelt so as not to affect the temperature of each house. Each set of pipes should have valves on both the flow and return, and as near the boiler as practicable. For connecting the houses with the boiler 1½-inch pipes answer very well, and they are preferably galvanised. The pipes within the houses for giving off heat should be 4-inch.

Training Vines to Upright Trellises (H. S.).—We do not think it would answer to train Vines to an upright trellis fixed across the house, as is sometimes done with Peach trees, for the Vines would be much in a position as those against a wall, the upper part so shading the lower by the over-hanging foliage; and though good results may be had from the upper part of the trellis, we fear the Vines on the lower portion would be so weak in growth as only to afford small bunches, if, indeed, they produced any. For a similar reason Vines do not succeed so well on the hack wall as when trained to a trellis 18 to 24 inches from the glass. We have, however, had very serviceable Grapes from a back wall, and also from Vines trained upright, but we did not compare the weight of the Grapes grown on that system with those trained to a trellis beneath the roof lights. It is solely a matter for experiment. If you adopt the upright trellises across the house they ought not to be less apart than 4 feet, and a double back-to-back trellis would not answer. About 1 lb. of Grapes per foot length of rod is a proper quantity for Vines to carry; but much depends on the condition of the Vines and the way they are treated as to feeding, &c. Peaches would succeed on the back wall of a vinery provided they are not too much shaded by the Vines; but if the Vines cover the roof the Peaches, though succeeding for two or three years, would for want of light thrive very indifferently.

Specimen Chrysanthemums (R. C.).—Mr. Hall of Brixton, the winner of several silver cups, and one of the best growers of specimen Chrysanthemums, wrote as follows in our columns five years ago, and he appears to have stated just what you want to know:—“The second week in March the plants will be about 6 inches in height and well established. I now take out the extreme point, which induce numerous side shoots to be thrown out—sometimes a dozen, according to the variety. I generally manage to have them potted into 6-inch pots by the middle of April; the side shoots or breaks are then about 5 or 6 inches long, and are pegged down towards the rim of the pot. Shortly after this the plants are removed to a cold frame, and plenty of air is given on all favourable occasions. At this time they grow very rapidly, and are again pinched and potted into 8-inch pots. I may here state that by taking out the extreme points of the shoots carefully I secure a larger number of strong breaks than by pinching back in a rough manner. If the

plants are allowed to have a check at this stage of their growth, either by hard pinching, allowing them to become dry, or placing them in cold draughts, they will eventually present the grower with a number of deformed flowers, besides losing a part of their foliage. I pot my plants for the last time from 8-inch to 11½-inch pots the first week in June, about which time they are pinched for the last time. This stopping will give from forty to sixty breaks, a number which will be found quite sufficient to form a first-class specimen. After being potted into their flowering pots they are taken to their summer quarters; a piece of open ground is provided in the full sun, but sheltered on all sides from wind. I place them on the surface of the ground, and surround each pot with ashes up to the rim. I let them grow on after this in their own wild way without any training whatever, giving them every day unlimited supplies of water, adding a little clear soot water two or three times a week. I find during hot weather that the plants cannot have too much water provided the drainage is clear. The foliage will also be improved by a watering overhead late every evening. Staking the plants is a very important operation, which requires care, taste, and patience. I usually commence tying the first week in October. I will, as briefly as possible, try to describe the way I proceed. The most convenient way is to place the plants on a handbarrow, being careful to have it level. But before tying I give a good dusting of flowers of sulphur underneath the foliage, which can be easily done by turning the plant on its side; this is to prevent mildew. The first stick placed in the centre of the plant must be upright. The sticks I use are about 2 feet long. I now take a shoot and tie it as low down this stick as I can without breaking—a little twisting is sometimes necessary—so that the bud comes directly on the top of the stick. Five sticks are now placed around this central stick in a circle, and they will be found to be about equal distance from the centre stick and from each other. The after-part is a mere repetition, except the outside circle, and these shoots are brought down to the rim of the pot and then tied straight up the stick. I allow my plants to stand outside as long as the weather is at all open, and several of the early varieties only have the protection of an open shed on wet days and cold nights. The plants will grow considerably after this, and the buds will soon be several inches above the sticks; these must be drawn down, carefully working the ties down at the same time until the bud reaches its original position, making a notch above each tie to prevent pushing up again. This mode of culture has led to considerable success both at metropolitan and suburban exhibitions." You will see by the above that the final tying is deferred long after the last potting. Some persons affix sticks across the pots, allowing the ends to extend as far as is desired, and to that is secured a circle of stout wire, to which the branches are secured. This is the method adopted in forming the heads of standard plants, which are not topped until they reach the intended height of the stem. The prices to which you refer are not the purchasing but the selling prices.

Names of Plants (C. D.).—1, *Eriostemon scabrum*; 2, *Hedera fuchsoides*; 3, *Boronia pinnata*; 4, *Boronia megastigma*. (*Salto*).—1, *Polypodium aureum*; 2, *Begonia maculata*; 3, *Begonia marga*. (*Reader*).—1, *Begonia nigricans*; 2, *B. metallica*; 3, *Daphne Laureola*. (*G. A. M.*).—1, *Withered*; 2, *A small Cypripedium Boxallii*; 3, *Libonia floribunda*; 4, *Maxillaria porphyrostele*.

COVENT GARDEN MARKET.—MARCH 12TH.

MARKET keeps quiet, and with Lent prices will suffer. Vegetables in good supply. First-class Apples in demand, common sorts heavy.

idea that corn would not pay for growing upon flat-lying strong land, which may or may not be true, according to varying circumstances over which the farmers have little or no control. One thing, however, may be taken as correct, that under the influence of a great mistake in the selection of seeds for the purpose of laying down land for permanent pasture, that an area corresponding with the popular idea entertained not only by the farmers, but the seedsmen also, has proved more or less a failure on all soils. As soon as the seeds of annuals and biennials sown in connection with the permanent grass seeds died away and left the land more or less bare, it induced the consequent belief that nothing but time and the waiting for Clovers and Grass indigenous to the soil to spring up could be done to repair the mischief, which has since been proved by all practical men to have been done by the mistakes referred to, of having seeded the land with Rye Grasses, none of which has proved permanent. In the consideration of reseeded we are confronted by the fact that variation in soils must have its effect upon the selection, as much as it has influenced us in recommending various seeds under the heading of "Seeds for Permanent Pasture on Different Soils." But again, there must, if a judicious selection is made, be some notice taken of those Grasses which are left, and which may fairly induce us to add more or less of other Grasses adapted for the soil. Still, on the other hand, we may consider the value of those sorts which have survived, and the non-value of those which have died out, yet we can hardly go so far as to say that the remaining plants are actually the survival of the fittest unless we knew the actual combination of seeds sown in the first instance.

We must now notice other causes of the infertility of portions of pastures under various circumstances, such as the growth and prevalence of inferior Grasses and weeds. Upon strong land we noticed that the Blue Carnation Grass (*Carex*) is prevalent. This at once denotes poverty, and that the deficiency is caused by the land being too poor to maintain the better Grasses, although some of them may have previously existed as indigenous to the soil, yet could not be retained without sufficient condition being present in the soil. This we have noticed as the frequent result of dairy cattle feeding without getting any cake, &c., in their rations of fodder, and at the same time the pasture not being cared for by manuring sufficiently to sustain the better Grasses. Again, there is another serious obstacle to production on park and pasture lands—viz., the growth of moss, which, although it seems frequently of a very dwarf habit of growth, yet it only shows that this moss is neither more nor less than the last effort of nature to clothe the land when it is so wanting in fertility that the superior herbage required for profitable production has entirely died out, arising from the cause we have before assigned—that of neglect.

Next we must consider the practical point of preparing the land for the reception of those seeds we may deem desirable for renovating, or whether we should dive deeper into expenses by breaking-up such inferior pasture and cultivating for saleable crops during three or four years, adding sufficient manure and chalk as may be required to make it productive when seeded with permanent pasture Grass seeds, and after being cultivated we may sometimes discover that portions of the field cannot be profitably treated without being drained. This is rather enlarging upon our subject, but the consideration of these points before seeding the land is only a practical and carefully devised matter to prevent future failures in the outlay for procuring good pasturage. We have often seen it noticed that the fact of moss being found on the land shows that it requires draining; but this may or may not be the case, for we can only say that except in the case of actual peat bogs it is really, as we have stated, caused by the absence of fertility in the land, whether it requires draining or not. We have found it existing on the driest soils as well as on the cold flat-lying clay lands, which would probably pay best for being drained before we could expect a superior turf for permanent pasture.

Let us now consider the best time of year for sowing the Grass seeds for renovating, preparing the land for reception of the seed, and also the sorts and quantity of manures per acre, and the time and manner of their application. Some farmers advocate the seeding to renovate defective pastures should be done just after a crop of hay has been removed. We, however, prefer to sow the seeds in the month of March, in order that the young plants may obtain a firm rooting before the winter begins. It is also found that in March we are pretty sure to find moisture enough to vegetate all the seeds which are sowed. Before sowing, however, the land should be first dragged with heavy iron drags two or three times, according to the state of the soil on the surface. If hard the more work should be done. It is also important as to whether the surface is clean or foul with moss or Couch. If by either of them, and there are no old Grass plants worth saving, the land may be scarified instead of dragged, and the Couch got together and carted away. When the land is clean and has been dragged the manure may be sown and harrowed in. The quantity of manure may vary, according to

SEEDS FOR RENOVATING PASTURES ON VARIOUS SOILS.

LARGE tracts of land during the past seven years have been laid into pasture under the influence of depression in agriculture, and the

the condition of the land, from 3 to 4 cwt. of bone superphosphate, and 2 to 2½ cwt. of nitrate of soda or Peruvian guano per acre. Nitrate if it is on light soil, guano if on heavy or loamy soil. After being worked-in by two tines of the harrows the land may then be rolled with the Cambridge ring roller. In that condition it may be seeded, as the grooves formed by the rings of the roller will be the means by which the seed may be buried, especially if the land is free-working and only a single tine of the chain harrow is given, for if several tines are given many seeds will appear on the surface. This work will not have destroyed any old plants which it may be desirable to save, except in case of the scarifier having been used.

The after management during the summer is a matter of extreme importance, and to justify our proposal of the management it must be remembered that on the surface the land not having been disturbed much we do not expect many weeds to appear, as they would on a regular fallow surface, therefore we advise that the young plants, together with any old ones which may have escaped during the working and seeding, should be allowed to grow up together until there is food enough to turn in some young store cattle. Care should be taken not to allow any sheep to feed on the land until the second year after seeding, nor should the young cattle be allowed to feed until the Grasses are strong, and the longer it is deferred the better until the Grasses will be rooted firmly enough to prevent their being pulled up. The feeding should not be long continued, only sufficient to pull off the tallest blades of Grasses. In some cases it may even be advisable to run the mowing machine over and take off any weeds and all Grasses which may have run up, and then leave the young Grass until necessity compels the feeding by young cattle, but dairy cows will sometimes be too strong and heavy treading for young seeds. If the land is very poor when the manure which is to be applied, 15 or 20 bushels of damp ashes should be mixed with the manures, which will prevent their flying before the wind at sowing time, and also tend to the more regular distribution of the manure. Still, in the next year, if the seeds do not appear strong, they should again be manured with a similar mixture of manures, or a mixture of earthy composts and dung, but more especially may this be necessary in the case of pastures having been overrun with moss, for except in those cases where the pasture has been recently made and the deficiencies have occurred through some of the plants having died out, we may be quite sure that the necessity for renovating has been caused by the land being too poor for producing the Grasses indigenous to the soil.

With regard to the seeds to be sown to renovate pastures which have failed to maintain a plant of Grass sufficient to make a turf, we must of course take notice of the soil to be seeded, as we have done in the seeding for certain soils, which have been fully described in the back numbers of this Journal dated February 21st, 28th, and March 6th of this year under the heading of "Seeds for Laying Down Land to Permanent Pasture;" and in order to simplify this matter, let the seeds as there named, both in sorts and quantities per acre, be sown in half quantities of those stated where there may be formed a partial or half a plant of the old or formerly seeded and survived plants. In case of those pastures which have been entirely cultivated on the surface to destroy moss or Couch, then we of course recommend for renovating the pasture so far as it is required by the entire loss and vacancy of the original turf, that the whole of the mixtures and quantities of each Grass seeds should be used, just as if we were laying down for a permanent pasture on a fallow in the first instance. On reference to the Journals of the dates above mentioned, the home farmer will find that we have with great care and caution endeavoured to adapt the seeds to the soils and purposes for which the pasture may be required, for where ornamental turf is partially required, as in parklands, the coarsest and most objectionable varieties for this purpose are omitted.

WORK ON THE HOME FARM.

Horse Labour.—This work is now very forward upon farms in general; for although the winter has been mild and stormy, yet generally speaking the rains have not been so continuous as in some former mild winters, and the drying intervals have proved the farmer's opportunity for forwarding the general work; although it must be admitted that intervals have not been obtained suitable for the drawing out heavy compost manures on the pastures. Whenever the manuring of Clovers or pastures could not be effected by carting on them and spreading earthy compost or well-decayed farmyard dung, now is the time for the application of artificial or hand-applied manures, and the best manures in mixture for either purpose will be found, if genuine, to be 2 cwt. of bone superphosphate and 1½ cwt. of nitrate of soda per acre. The late fine weather has induced us to thresh one rick of Wheat and one rick of white Victoria Oats, the yield not being so great as in the previous year. We take great care in ricking and thatching the straw, especially of these white Oats, for this is in great request for cutting into chaff, mixed with hay, by cab owners and omnibus proprietors in towns; and there is no doubt that it is of more value as fodder than either Barley or Wheat straw. The drilling of Oats, Peas and Beans has been in progress at every fine interval, and should be continued until finished; because if

delayed it may put off and delay the necessary tillage for Mangolds and other roots. Now is the time to prepare a border or headland for the seeding with Cabbage or Broccoli in districts where there is a sale for them, for we allude not to Broccoli to stand the winter and be sold in the spring months, for this delays the season for other crops which may succeed, but we mean autumn Giant Cauliflower, which will come off the land early enough to be sown with Wheat when the land is in high condition through liberal manuring. Bone superphosphate 4 cwt. per acre, and guano 4 cwt. on loamy land, but 2½ cwt. of nitrate of soda upon light soils per acre, we find are mixtures when used for either Potato, Cabbage, or Broccoli growing will prove better than any other kind of yard dung, town dung, or night soil. The last-named is, however, specially objectionable for Broccoli, for it is greatly complained of, proving very offensive after cooking when the roots are grown from night soil; it is, however, no matter for cattle, Cabbages, and Mangolds, and is no doubt the most powerful agent in producing luxuriant growth, which we have, except well apportioned mixtures of bone phosphates, guano, or nitrate of soda.

Hand Labour.—Trenching in the meadows should now be completed, and the regulation of the flood waters in irrigated meadows must be properly regulated, for in four weeks time the sheep on the hill farms will require the early food which they produce. Elm and Ash timber has been cut lately to a considerable extent, but it is now too late to continue this work. The cutting of underwood in the coppices should also be finished about this time, and also in the hedgerows where the materials are grown for making into hurdles and spar-wood. The men will now be required to finish the hedge-trimming, as some farmers reserve this work until the sap rises in the wood, as it cuts so much casier, and the hedges may be made more shapeable objects in consequence. At all fine intervals both men and women will be required in the fields planting Potatoes, and also forking out Couch before the sheep on the late Swede crops, so that when the land has been seeded in the Lent corn the Clovers may be found clean, and therefore preventing the farmers' pest from increasing, as every practical farmer is obliged to admit that forking-out Couch is not only the surest way of getting rid of it, but also the cheapest, just as hand labour in this matter is everywhere, when well directed, cheaper than horse labour.

Live Stock.—On account of the mildness of the winter both cattle and sheep have fared well in many pasture districts. The ewes of late lambing breeds, like the Downs and long-wools, have yeanned a healthy lot of lambs with more than an average number of twins. Now, to our mind, the fattening of young sucking lambs is more important at present than any other method of sheep feeding, for the simple reason that not only are they yielding the quickest return for both food and labour, but they go to market and are sold without meeting with any foreign competition. This cannot be said of scarcely any other kind of stock fed by the farmer, and we think this point is frequently not only lost sight of, but in consequence not turned to the good account which it may be. Dairy cows are now calving fast in the dairy districts where cheese-making is practised, and also in the butter-making dairies it is the popular period, if we may so term it, for the cows to calve; in fact, we may go farther and say that it is a prejudice in the minds of farmers that the cows should calve in the spring, which goes far to account for the circumstance that fresh butter is cheaper in the summer, and scarcely to be obtained at all in the winter months. This is a matter serious enough in the farmers' interest, and ought to make him think upon this matter, in order to turn his milk and cream production into a more profitable and better regulated supply, with benefit to himself and the consumer also, especially as in the future there is every prospect of ensilage being one of the great factors in butter-making during the winter months for all cows which may calve in October or November. The root crops are holding out well for the sheep, and it is a question to be considered whether a portion of them should not be removed and stored for use, or used immediately for the fattening bullocks, so that the Lent corn crops to follow may be sown at an earlier date.

REMARKS.

2nd.—Fine and bright throughout.
3rd.—Cold small rain began at 10 A.M.; it continued nearly all day, but became warmer in evening.
4th.—Wet morning, fine after, and windy in evening.
5th.—Very bright all day, with hot sun.
6th.—Fair early, and fine after 11 A.M.
7th.—Fog early, then fine all day.
8th.—Fine in morning (with some fog); slight rain after 3 P.M.; fine evening. (Heavy rain in early morning of 9th.)
Temperature near the average, and slight frosts on several nights.—G. J. YMONS.]

PLANTS FROM SEED FOR CUT FLOWERS.

IT is notable that plants raised from seed are freer in growth and more floriferous than those raised from cuttings or layers—that they are for general decorative purposes and cutting from greatly superior to the florists' varieties, and except for particular purposes and to meet some standard ideas are in every way preferable for general acceptance. It is not intended to convey an impression that seedlings are equal in beauty of form and other properties to be found in a flower as it meets a florists' idea of quality, but it must be admitted that the plants raised from seed carefully selected from superior flowers afford very different results, and much better than were obtainable a few years ago. Nine out of every ten persons only value flowers for their effectiveness in the garden and their usefulness for the ornamentation of the house. The florist may look at the variety of colour and form presented by the mixed border, and yet pass the flowers as beneath his notice from a "florist's point of view;" yet those who want flowers, whether on the plant for effect or in a cut state to provide a chaste, elegant, graceful, and pleasing arrangement, must look for them in the mixed border. No one knows this better than florists, and it is to their care and skill that we owe the vastly improved forms of flowers that are now raised from seed, many of which very closely approach the florist's standard of excellence. This is only what might be anticipated, for it is practically impossible for a true lover of flowers to keep from improving whatever he takes in hand. Be this as it may, several years' experience enables me to say as much enjoyment can be had for the expenditure involved in purchasing a packet of seed as from a considerably larger amount invested in plants, dozens of plants being had for the money that is often necessary to purchase one example of a named variety, while the seedlings give a more pleasing and useful display of flowers. I do not wish for a moment to disparage named varieties, as they are or have been seedlings that have been continued by propagation other than by seed, because they gave excellence in advance of the majority of the seedlings; yet so great has been the advance in seed-saving and the efforts to improve the strains of flowers, that seedlings as now obtained exhibit a decided improvement and fixedness of character that was looked for in vain a few years ago. Indeed, so fixed have some of the forms become that our principal seedsmen are able to offer distinct varieties of several kinds as coming true from seed.

There is another important point in raising plants from seed—viz., greater facility for effecting the desired object. There is no need to winter plants, as the seed is much more easily kept over the winter, and if the plants are biennial or perennial they stand outdoors, where the choicer sorts must have frame protection. Seedlings are less trouble in propagation, require less care afterwards, and if the strain be good the display of flowers is always satisfactory. The subject would be best treated under two heads—

1, Annuals, including such biennials or perennials as flower freely the first year; 2, Those which under ordinary treatment do not flower freely, or only late in the season under special treatment the first year, and need to be treated as biennials. I must, however, point out that most plants raised from seed are with some exceptions, which will be noted as we proceed, of very little use after their flowering is over, and should be destroyed.

SINGLE DAHLIAS.—These are quite unique for cutting purposes, and are probably the most beautiful of border plants. If the seed be sown in March in a hotbed, and the plants kept near the glass, potted off singly when they are showing the second leaves, and grown on in frames or in a greenhouse after they become established after potting, good plants will be had by the end of May, and when put out they will bloom well until early August and until frost comes. The seed may be had in separate varieties, but it does not do to place implicit reliance on them, as they may come true, but sometimes do not. The most fixed appear to be Paragon, Cervantesi, Harlequin, Sunset, White Queen, and Yellow Gem. The mixed packets give a great number of colours. The plants make an excellent back row to a border, and for large beds are beautiful.

CORNFLOWER (*Centaurea cyanus major*).—There are several varieties of this, but the blue is far the best. Everybody knows it, and yet it is not so much grown as it ought to be. The seed should be sown early in April in the open border in patches for a mixed border about a foot across and 2 feet apart, thinning the plants so as to leave half a dozen of the strongest in each patch. It will grow 3 feet high and forms a good row next to the single Dahlias, its blue tint contrasting well with their shades of red, white, and yellow. The plants are all the better for being secured to stakes, but must not be "bundled" or the plants will be spoiled if a wet time sets in. To have early flowers sow in September in a warm sheltered spot and transplant in spring.

SINGLE CHRYSANTHEMUMS.—These are showy and effective, blooming profusely and continuously until frost. The flowers exhibit a great range of colours, and are 2 to 3 inches across, circular in outline, and good in substance. The seed should be sown in patches like the Cornflowers, as they then make fine clumps, and for cutting are unequalled. They grow 2½ to 3 feet in height. The seed should be sown early in April where the plants are to remain. The following are the best:—*C. segetum*, bright yellow; *C. leucanthemum*, white, yellow centre; and the varieties of *C. tricolor*—viz., *luteum*; Lord Beaconsfield, crimson edged gold, dwarf; W. E. Gladstone, crimson; The Sultan, crimson-maroon; *atro-coccineum*, scarlet; *venustum*, crimson and white; *carinatum* or *tricolor*, white and yellow; and *Burridgeanum*, white, crimson, and yellow. These make a grand display and bear examination in any position. They are also useful when grown in pots.

ZINNIAS.—The single and double-flowered varieties are very bright in colour in various shades of scarlet, crimson, red, and white, and are effective either as border plants or the flowers for cutting. They grow 2 to 2½ feet high.

ASTERS.—Truffaut's Perfection *Pæony*-flowered in twelve distinct colours, Victoria in twelve distinct colours, Rose-flowered in ten distinct varieties, and Read's Quilled Improved (Betteridge) in sixteen distinct colours, are beautiful plants when well grown. The first three grow 1½ to 2 feet in height, and the last to 2½ to 3 feet in rich soil. The prevailing colours are purple or blue shades, rose, carmine, crimson, and white, or a combination of two colours, such as blue and white, crimson and white.

DWARF SCABIOUS.—These attain a height of about 2 feet, and are white, blush, rose, up to deep velvety crimson. They are very free-flowering, forming much-branched plants, and continue in bloom up to frost. The flowers are very effective and are fine for cutting, having long stems, and are sweetly scented.

FRENCH MARIGOLD.—Seedsmen have selected strains of

those that may be relied on for producing flowers bright in colour and very effective; the scent is far less strong than many flowers that are esteemed for their powerful odour. They grow to a height of 2 to 2½ feet.

The Zinnias, Asters, Scabious, and Marigolds form good third-row plants, and should be planted about 18 inches apart, or five in a patch about a foot across, with 2 feet spaces between.

STOCKS.—The large-flowering German, scarlet, purple, and white are the best; the large-flowering German Victoria, scarlet, being very fine. There are many other shades of colour, but these are the most useful. They grow about 18 inches high, and are useful for cutting, being much prized for their delightful fragrance.

PHLOX DRUMMONDI.—There are twelve distinctly coloured varieties of this plant, the prevailing shades being white, deep scarlet or crimson, purple, white and crimson, rose, and striped or splashed in various shades. The large-flowered or grandiflora section are the best. They are about 18 inches high.

Dianthus chinensis of varied shades of colour are very beautiful and useful for cutting. They grow about 18 inches high, and form with the Phlox an admirable fourth row at 18 inches distance apart.

All those named from Zinnia down to Dianthus are half-hardy, and the seed should be sown in a frame early in April, and if on a hotbed 18 inches to 2 feet high of sweetened leaves and litter, it will be an advantage, but the heat is not absolutely necessary. The frame should be stood in a warm situation on a bed of ashes, and 6 inches of rich light soil placed in it, and, if at all dry, it must be brought into a good moist condition before sowing the seed. Sow in drills about 3 inches apart, varying the depth to suit the different sizes of seed, in all cases covering them about the same depth as the diameter of the seeds. Keep the frame closed until the seedlings appear, shading from bright sun to prevent the soil drying, but avoid too frequent waterings, as all that is necessary is to keep the soil moist. When the plants appear admit air freely if the weather is bright or mild, and cover with mats at night as a safeguard against frost. The plants must be kept in a growing state by watering as necessary, avoiding a very moist soil or moist close atmosphere, which has a tendency to make the plants soft, and some will then damp off, particularly Stocks. After the seedlings show the second leaves they may be damped through a fine rose, closing the frame early, and they will grow quickly and strongly. After the middle of May the lights may be withdrawn on mild fine days, and by the close of that month they may be planted out, or soon after, as a showery time determine. This method is far better than sowing seed in pans, pricking off the seedlings and growing them on in heat; but it is necessary that the seed be sown rather thinly, so as to obviate the necessity for pricking off.

SWEET SULTAN.—These are more useful than showy, being fine for cutting, as the flowers have long stalks and are sweet-scented. They grow 2 to 2½ feet high, and should be sown early in April, where they are to remain in patches about 1 foot across and 2 feet between, thinning out to about half a dozen in a batch. They make capital second-row plants with the Cornflower and Chrysanthemum, next to the single Dahlias. For early summer blooming sow in early September.

ESCHSCHOLTZIA.—*E. californica*, *E. crocea*, *E. crocea alba*, *E. crocea flore-pleno*, *E. carminea*, *E. rosea*, and *E. Mandarin* are fine for cutting, being very showy if only when the buds are opening, flowering until frost is experienced. Sow seed in patches early in April.

VERBENA HYBRIDA.—Sow seed in pans in March or early April, place in a hotbed, and grow the plants in gentle warmth, pricking off when large enough, and harden off for planting out about 18 inches apart at the close of May or early in June. These with the Eschscholtzias make good fifth-row plants, or the one next the edge or path but one, and if the

flowers do not equal the named varieties they give very fine trusses, and are useful for cutting.

MIGNONETTE.—Of this we have many varieties. Dwarf Erect, with stout spikes and red flowers; Golden Queen, Crimson King, Garaway's White, Miles' Spiral, and Queen Victoria. Sow in the same line as the Eschscholtzias and Verbenas in early April, and thin well out, as the finest spikes are only borne by the sturdiest plants.

PANSY.—The large-flowered English, large-flowered Fancy or Belgian, and large-flowered German Pansies, should be sown similarly to half-hardy annuals, and planted out when fit as a front row or edging, mixing them, and about a foot from the edge. These will please everybody, and the German variety is sweet-scented.

In these notes I have had in view a border which from July to late autumn produced an unrivalled display, and at the same time afforded cartloads of flowers. They are popular, even fashionable, and cheap, within the reach of all. To make the border complete have *Tropaeolum Lobbianum* var. behind the Dahlias, trained to stakes 6 feet high and about 4 feet apart. These should be sown early in April in pots in a frame, potted off singly or in threes, and put out at the close of May or early in June. In the intermediate space, and that between the Dahlias and Sweet Peas, Mignonette should be sown about the middle of April, and we then have a carpet of the sweetest floral essence, and one that will be charming all day long with the merry hum of bees. There should be a back row or hedge of Sweet Peas sown about the middle of April or not later than early May. Secure them to sticks that are high enough, as nothing looks so bad as a leaning background or with the top half over.

To make the most of the flowers that such a border will give it will be advisable to grow some of the ornamental Grasses to intersperse with the flowers in setting up, for they impart a gracefulness that is most pleasing.—G. ABBEY.

NOTES ON ORCHIDS.

SHADING ORCHIDS.—The idea that many of our coolest *Odontoglossums* required to be kept from the reach of sunshine has now about passed away, and we are having abundance of proofs that this idea was a wrong one. In this country the sun's rays, even after passing through glass, are not nearly so powerful as they are in the tropical zone where cool *Odontoglossums* are found, albeit at such an elevation as keeps them cool. In the middle of our summer season shade is an advantage to many Orchids, but during winter all the light possible is required to keep the plants strong. High up on the mountains of Central America the air is brisk and rarified, and the light is clear even under the shade of forests. A dark, damp, stuffy house, built in such a way as to exclude all sunshine except during summer when thick blinds are used, is hardly the place in which plants hailing from the districts mentioned would be at home. The sun will not hurt any Orchid in winter, and in summer all that cool *Odontoglossums* require is protection from powerful mid-day sun. With a free circulation of air no sun heat can do harm to Orchids; on the contrary, it is essential to their welfare, and therefore the coolest *Odontoglossum* will be happy in a house where the most powerful sunlight only is excluded, but where the sun's heat and a free circulation of air without draught are allowed to enter.—ERIA.

THUNIAS.—If carefully wintered in a cool temperature these plants should now be showing signs of new growth. We have just repotted ours, and find them in a promising condition, the old pseudo-bulbs being firm and plump, and the new buds thick and strong as Bamboo buds. For compost we prefer fibry loam and peat, equal parts, with a sprinkling of dried cowdung. If manure is not used in a solid state it will be necessary to supply the plants with it in solution as growth proceeds, Thunias being gross feeders. Unless this food is supplied the new pseudo-bulbs will be attenuated and probably fail to flower. If placed in a warm moist stove near the glass, and liberally supplied with water both at the root and overhead, these plants grow very rapidly and will flower in midsummer. *T. alba*, *T. Bensoni*, and *T. Marshalli* may be rested in a cool frame or house during the winter; but *T. formosa*, or rather a plant which we have under that name, will rot if kept in a low temperature. We have lost the bases of our plants this year through treating them as we

do the others. Can anyone give me any information about this plant? I had the name from the late Mr. Spyers, but neither he nor anyone I have hitherto inquired of knew anything of the flowers. The bulbs of the *Thunias* may be cut into lengths and placed in sand or peat fibre, in which they seldom fail to strike root.

BLETIAS.—The Japanese *B. hyacinthina* should now be pushing up its growths, and if kept in a frame or greenhouse near the glass they will be strong and produce flowers freely. As a rule this plant is grown in too much heat. It is almost hardy in this country, and therefore is never happy in a warm house. If potted in a mixture of peat and loam and kept rather moist at all times except during midwinter, feeding it a little now and again with liquid manure during its growing season, this species may be left in the same pot for several years. I have found that shaking the plants out of the old soil and repotting them has a bad effect on their health. *B. Shepherdii*, a large purple-flowered species from Jamaica, requires much more warmth than the Japanese one. We wintered ours along with the *Thunias*, and find them now plump and promising. The mixture advised for the *Thunias* suits also this *Bletia*, which after potting should be placed in the *Cattleya* house, where it will soon develop both leaves and flowers. The latter are as large as a *Lælia pumila* flower, and are very handsome.

PHAIUS GRANDIFOLIUS.—This is now in flower, its large-flowered spikes towering up above the lower plants and showing themselves with fine effect. *P. Wallichii* is also blooming in the same way. Both these plants are great favourites with us, although in many good gardens they are looked upon as weedy. It would be difficult to find a more ornamental plant than a large well-managed specimen of either of these with half a dozen strong spikes of flowers. To lovers of good old plants I would recommend a few large pots of these two plants if they do not already possess them. Planted in loam and cowdung in large roomy pots, and placed in a vinery or Peach house to make their growth, they will by the autumn be strong enough to produce spikes 4 feet long. Both plants are very accommodating as regards position. They will grow anywhere where there is heat and moisture, though, of course, a moderately light position suits them best. In the tropics they are used as bedding plants, much as we use the *Cardinal Lobelia*. We have *P. luridus* from Ceylon now showing its flower spikes. This species we grow in the tropical house. The handsome *P. tuberculatus* we do not at present possess, though from what is said of it there can be little doubt of its merits.

DISA GRANDIFLORA.—Is tobacco smoke injurious to these plants? Up to last week our plants were in every way satisfactory, strong, healthy, and without a spot or a brown tip; but a day or so after a mild fumigating in the house where the *Disas* stand the tips of the leaves turned brown, and they are now looking a little sickly. Green fly is fond of this plant—so fond, in fact, that unless some antidote is frequently applied they are certain to gain a strong footing. It is not always easy to find out whether tobacco smoke does harm, and I am inclined to believe that its ill effects are not unfrequently attributed to some other cause. For instance, what causes many *Masdevallias* to turn black under the leaves and look so very unsightly? A friend suggested that it was most likely the effect of tobacco smoke on the leaves when young, and that the marks did not show until the foliage ripened. Most growers fumigate their *Masdevallias* more or less often, and very few, if any, growers can show old plants unaffected by black spot. Of course this suggestion may be quite wrong, but to me, with my experience of what smoke will do, it seems not unworthy of consideration.—W. W.

ONCIDIUM CONCOLOR.—A very pretty and useful Orchid for cutting. I find it does best when grown in baskets hung close to the glass in the *Cattleya* house, or in any structure that is kept at an intermediate temperature.

SOPHRONITIS GRANDIFLORA.—This Orchid is often recommended to be grown in a cool temperature, but I have found it to succeed best in pots placed in a basket and hung in an intermediate house. The blooms are brighter in colour and twice the size than when grown in a cool house.

LÆLIA AUTUMNALIS.—Many gardeners find a difficulty in growing the above useful plant successfully. I have found it best when in a cool house close to the glass and without shade. The same treatment suits *Lælia majalis* admirably.—A GROWER.

ONCIDIUM SARCODES.—About a year and a half ago I received direct from Brazil a box of Orchids, among which was the above variety. They were packed in wood shavings and nearly dried up. I potted them, and now they are healthy

plants. *Oncidium sarcodes* has a spike of bloom on it nearly 4 feet long.—H.

CUTTING DOWN DENDROBIUMS.—At page 204 I notice that "B." states he has been very successful in cutting down *Dendrobiums*; but this is so different from my own experience and that of many other growers who have tried the experiment, that it would be very interesting if he would favour us with particulars as to his mode of treatment. Does he remove all the old pseudo-bulbs? If so, when are they cut down, and how long has he practised the system?—C.

ORCHID SALE.—Last week Mr. J. Stevens held a large sale of Orchids at King Street, Covent Garden, over 400 lots being entered. *Cattleyas*, *Odontoglossums*, and *Dendrobiums* were numerous represented, and some good prices were realised. Some of the best varieties of *Cattleya Trianae* were sold for sums varying from £3 to £16 according to their quality. Varieties of *Odontoglossum Alexandrae* realised from £3 to £10, one exceptionally fine form with large pure white flowers being sold for £16 5s. A plant of the *Trentham* variety of *Odontoglossum Rossi majus* was sold for £13 2s. 6d. Plants of *O. Andersonianum*, *O. Halli*, and *O. triumphans* fetched four to five guineas each. Some unnamed *Odontoglossums* were included in the sale, and one dark-flowered form realised £17, others being sold at proportionate prices. A rosy-flushed variety of *O. Pescatorei*, very beautiful and distinct, was knocked down at £7 17s., while a small plant of *Lycaste Skinneri alba* was sold at ten guineas. The majority of the plants were in flower, and some in very fine condition, a display of great interest being formed; indeed these Orchid sales increase in interest, and are assuming the proportions of exhibitions.

Messrs. Protheroe & Morris held a sale of imported Orchids at their rooms, Cheapside, on the Friday following. The plants offered included *Odontoglossum polyanthum*, which was sold at moderate prices, some of the best realising three or four guineas. *O. ramosissimum*, a difficult Orchid to import, was in very good condition, and the prices were similar to the preceding. *Nanodes Medusæ* was mostly promising, and fair prices were realised for the best.

SIEBOLD'S PRIMROSE.

DURING a somewhat varied experience of hardy plants I have often been asked to give a reason for the disappearance of this plant, without in many cases any apparent cause. This, combined with a wide-spread belief that the plant is not thoroughly hardy, has tended to bring it into bad repute with gardeners. The plant, however, is perfectly hardy, and if given a proper soil and situation none will produce a more brilliant and varied display than this and its numerous varieties.

This member of the genus *Primula* has been somewhat unfortunate as regards its name, various authorities having called it *P. cortusoides amoena* (Hook.), *P. amoena* (Hort.), *P. Veitchii* (Rob.), *P. Sieboldi* (Lehm.). The two former might be discarded on the ground that it is perfectly distinct from either, the latter plant not being as yet in cultivation, and *P. Veitchii* having to yield to *Lehmann's* name on the score of priority. This plant was introduced into cultivation by the late Mr. J. G. Veitch from Japan. It produces its flowers in April and May on slender stalks about 1 foot in height, bearing an umbel of from six to twelve flowers each on its own little pedicel. In the type the colour is a rich rose with a white eye, but this is very variable. The corolla is from 1½ to 2 inches in diameter. The capsule is grooved, and the seeds roundish and flattened. The leaves are ovate acute, occasionally cordate at the base, about 3 inches in length by 2 in breadth, coarsely toothed and hairy. Being of a delicate texture they are apt to be broken when exposed to rough winds.

To insure success with this plant all that is necessary is to secure a place moderately shaded from the direct rays of the midday sun and well drained, taking out the soil to a depth of 9 to 12 inches, and placing a layer of broken pots or stones, if necessary, to prevent the stagnation of water around the roots. A mixture of ordinary garden soil and leaf mould in equal proportions, with a little sand if too heavy, as in this case it is better to have the mixture too light than the reverse, will be all that is necessary. But the whole secret of success lies in the manner in which they are planted, which cannot be too carefully attended to. Unlike most *Primulas*, this plant forms a series of prostrate stems, from the under surface of which the fibrous roots are emitted, each stem branching off in various directions, each one having a bud at its extremity. These branches should be carefully divided about this season just as they are commencing to make their annual growth, and planted in such a manner that the stem rests flat upon the surface, or so nearly that

the first shower will leave them fully exposed upon the surface in the manner of a German Iris, while the actual roots are put right down into the soil, there to ramble about. This full exposure of the stems to the light and air causes them to be firm and well matured, fit to resist the cold and damp of winter, and in cold soils or low and humid situations a very slight covering of finely sifted coal ashes applied about the end of October, though not sufficient to afford any great protection, is yet very beneficial in its effects. If so treated they may be allowed to remain for several years without division or removal, and will form a dense mass of closely interlaced stems, producing annually sheets of bright flowers and attractive foliage. The varieties best adapted for outdoor growth will now be mentioned, the writer being careful to notice only such plants as have been well tested in various localities, especially during the winters of 1879-80 and 1880-81, although there is no doubt but what the newer varieties will prove equally hardy when they become sufficiently common for strong plants to be procurable.

Primula Sieboldi.—This, which is usually considered the type, is moderately strong in growth, having flowers of a rich rose colour, with white eye.

P. grandiflora.—Larger flowers, of a French white internally, but bright rose without. This and the next have drooping flowers, but are stronger growers than the type.

P. grandiflora alba.—A fac-simile of the preceding, but with pure white flowers.

P. intermedia.—Smaller in all respects but that of height than the type, but with the petals much narrower in proportion to their length, giving it a very distinct and what is often called starry appearance.

P. intermedia alba.—A pure white form of the preceding.

P. fimbriata oculata.—Flowers bright violet, with a white eye. This variety has the petals closely serrated and numerous fine lines of white from the eye running into the petals; very distinct.

P. lilacina.—Large lilac blooms, with the petals coarsely toothed and fringed, the margins frequently overlapping at the sides in regular order, giving the bloom somewhat the appearance of an abortive attempt to produce a semi-double flower.

This list might be easily extended, giving a much greater variety of colour, but anyone having been successful with these will no doubt be tempted to procure a more varied selection.—KENT.

A PLAGUE OF MILLEPEDES.

I HAVE sent you a small box with some Beans in it swarming with insects that have infested my garden since the summer of 1882. They were first noticed that summer in the Strawberries. In them they only make a hole the size of a knitting needle, often close on a hundred of the worms being found in a Strawberry. I took up the whole lot of Strawberries, severely salted and dug in salt. Two weeks after I severely sooted and limed all the ground, then replanted Strawberries. Last season the pests were much more numerous, and hundreds of Strawberry fruits were destroyed. They also attacked a few of the Potatoes. I found them in roots of Globe Artichokes, all this wet winter in the Celery, also in Carrots, also in all the Apples and Pears and Plums that were a night on orchard grass after wind, also in a few Dahlia roots when taking them up. Last November when digging all the garden it was heavily salted. On planting these Beans the ground was limed and sooted, the Beans and Peas were soaked for two hours in a basin with half petroleum, some softsoap and half water, and were greasy and wet when put into the ground. Not seeing any Beans coming we took them up this day, found forty-nine of them rotting, and all infested as those I send you. I also found them at the roots of some choice Pansies along with the leather grub. The Pansy bed, after being cleared of plants, was deluged with extra strong solutions of petroleum and softsoap, half of those and half water; now the Pansies in the same bed look healthy and strong. The pests further attacked Nectarines and Peaches on the ground last autumn that escaped falling into the nets to receive them. I think I have done everything thirty years' experience has taught me, along with all the valuable hints I have had during the last ten years from the Journal. I am now utterly beaten by the reptile I send you, and can only think of burning the surface of the entire garden, which of course no one can do, nor any part of it now or for this season after the six weeks' deluge of rain, the ground all over this locality being water-sopped and unable to let down the rainfall of this last week. I apologise for the length of this information I send of this pest, but all my neighbours are much in the same boat, and I can neither find out what the beast is or how to get rid of it. Again, I say, pray excuse a suffering inquirer.—SAXORING.

N.B.—For four years since I began wasbing Beans and Peas in strong solution of petroleum I have never lost one, and always till now had splendid crops of Peas.

[The reptiles infesting the Beans are millepedes. From reports that have reached us it appears that this spring much mischief has been done in some gardens by various species of this garden pest. It has been noticed by naturalists that most insects, even subterranean feeders, are

sufferers by such a mild and damp winter as that of last season, but the species of *Julus* are evidently none the worse for it; and probably, as a rule, all the year round those gardens that are insufficiently drained are likely to be harbourers of the pests. The commonest species are *J. pulchellus*, so called from a double row of crimson spots along the back, a very small but active species; and *J. terrestris*, a larger insect, of a brown or reddish-brown colour, and which, if less numerous than its relative, makes up for this by its size. It is also supposed to live and feed for nearly two years. These and other species of *Julus* destroy slugs, smaller insects, and decayed vegetable substances. Their taste for variety, however, leads them to attack bulbs and corms, also newly sown Beans and Peas, the roots of Cabbages, and many other plants. Hence it is necessary to take measures against them, as by setting traps, pots being loosely filled with such articles as are likely to attract them, moist rotting roots, damaged Potatoes or Apples, &c. Numerous we know are the compounds recommended for destroying root-feeders; but the *Julidæ* are so tough, and cling so closely to the object they are attacking, that it is difficult to kill them without damaging the plants. We fancy bellebore tea would be sometimes efficacious. In potting, when there is reason to suspect that small millepedes may be present in the soil, this should be baked before using. In bad cases ground may be so infested with them as to need dressing with sulphuric acid, to the destruction of all animal and vegetable life. They seem to have few natural enemies. Birds seldom meddle with them. Our correspondent has himself indicated one of the best remedies—petroleum. This applied to the infested ground the same as it was applied to the Pansy bed would also probably have a similar effect in extirpating the pest, and act as a manure for the crops succeeding. The soil also probably needs draining, and should be thrown into ridges in the autumn to the action of frost, breaking the crust whenever possible, to expose the greatest possible quantity of the soil to the severity of the weather. Burning the soil would be efficacious, but that at present is out of the question.]

THE GARDENERS' ROYAL BENEVOLENT INSTITUTION.

I AM very sorry I have not been able to send Mr. Cutler the information he asked for. On reading his communication in November last I wrote at once to my friend for all particulars and permission to forward his name, &c., to Mr. Cutler, that the Committee might inquire into the case. He did not reply. I wrote a second time, but have received no reply. I waited, hoping to have an opportunity of seeing him personally, but have not been able to do so thus far, as the last time I heard anything of him he was living nearly 100 miles from here, and he is now old and probably in feeble health, so that I do not wish to trouble him more than is necessary. The member of the society whom he spoke to for assistance on the subject has been dead for some time, so that his name need not be mentioned; and here is probably where the mistake occurred through my friend not applying to the Secretary in the usual way. It seems from what has been published on the subject since I first wrote he would have then obtained a very different answer. Why he did not pursue the subject any farther I know not; perhaps his circumstances improved. At any rate he did not appear to trouble himself any farther, and contrived to do without the assistance of the Society.

It will now be seen how I have been misled, as he told the case to me and a friend as stated, and now withholds permission for me to move any farther in the matter; but as I stated in your issue of November 29th last I was not writing on his behalf in any way. If he still required the assistance of the Society he would doubtless have used some of the means mentioned by Mr. Cutler for obtaining it, or if he had requested me to move in the matter for him I should certainly have applied to Mr. Cutler in the first place.

I do not allow my imagination to run riot when I take up the pen; on the contrary, no one dislikes fiction of all kinds more than myself; but, as stated at the time, "I wrote for information for myself and also for others" on a subject which the rules of the Society gave, practically speaking, no information whatever, as I fully intended joining the Institution as soon as my circumstances permitted if I received a favourable reply. And I was thus giving the Secretary an opportunity to clear up a dark question and advance the claims of his Society before the public, as I felt most likely the same difficulty had appeared to others as well as myself (which conclusion was afterwards justified by another correspondent), and I merely mentioned the case as an example of the information I wanted, and knowing it is more convenient for many to pay down a sum of £10 10s. at once when young than to keep up an annual subscription of £1 1s. through life under varying circumstances, "provided each gave equal advantages." These were my sole motives for asking for the information. Most certainly I had not the least wish to disparage an institution which I know has done so much good to members of my vocation.

In conclusion, if anything I have at any time written has in any way prejudiced the Institution or anyone connected therewith I fully apologise for the same. Speaking for myself I have more confidence in the Society now than I ever had, and I sincerely hope everyone else has also.—W. H. DIVERS.

CONTROVERSY.—Acting on the principle I suggested to others when writing on this subject before, I do not reply to "C. W.'s" irrelevant question (page 208) concerning Vine shoots, but advise him to find out why the contents were put into the bottles in the first instance, and why the Vine shoots were inserted in these contents. When he has discovered the reason of this he will learn how the shoots grew and were supported also. The form in which "C. W.'s" question is put now leads towards

one of those irrelevant side issues I cautioned readers against before, and which I have not time nor inclination to follow.—CASUAL.

[We doubt if "C. W." will have either time or inclination to "follow" this note.]

TRILLIUMS.

THE genus *Trillium* includes some of the most beautiful and useful hardy plants we possess; unfortunately they have gained the reputation of being difficult to cultivate, and in consequence they are not so common in gardens as they might otherwise be. As regards the soil in which they are grown they are not at all fastidious, although in most cases they prefer a peaty soil; *T. grandiflorum*, for instance, will succeed fairly in ordinary loam in partially shady positions. The soil should be deep, and it is absolutely necessary to have it well drained, as they are most averse to stagnant moisture at their roots. In an artificial bog they thrive admirably, and although the increase is slow it is always sure when once they are well established. They are also very useful for edging beds of *Azaleas*, *Kalmias*, and low-growing *Rhododendrons*; and *T. grandiflorum* especially has been very effectively used as an edging for clumps of *Pernettyas*, the shade and protection from cold winds being in these cases quite sufficient for their well-being. Few plants are better fitted than *Trilliums* for shady positions, and it is a matter of regret that no one has given them a chance to naturalise themselves on a large scale

Fig. 47.—*Trillium erectum*, var. *atropurpureum*.

in wild gardens or by the edge of shady walks, as they come into flower just after the *Crocuses* and *Snowdrops* are past.

Trillium grandiflorum is an extremely handsome and singular plant. It grows from 1 foot to 18 inches in height, and the leaves, which are three in number, are borne in a whorl umbrella fashion near the summit of the stem; they are broadly ovate, and of a dark shining green colour, having well-marked veins. The flowers, of which there is one to each stem, spring from the centre of the whorl of leaves, and are supported on short stalks in a slightly drooping position. The three petals are ivory white, and the sepals, although generally green, at times vary to cream or whitish. This species has been grown with considerable success as a pot plant, and as it flowers early in April, through May and June, is very useful for that purpose. Native of the Northern United States, where it is found plentifully in rich woods.

T. erythrocarpum, the Painted *Trillium*, is the most striking and beautiful species of the group, far surpassing any of them, but is unfortunately an extremely shy flowerer; the leaves are more inclined to lanceolate than any of the others, bright green, taper-pointed, with vivid purple margins. The petals are wavy at the edges and widely spreading, pure white, with rosy purple streaks reaching half their length; they are almost twice as long as the sepals. It is found in the cold damp woods and bogs along Lake Superior. It would be a magnificent plant for naturalising. It flowers in May and June.

T. erectum, the Purple Birthroot, is one of the most variable of all, some of the forms having large reddish purple flowers in all shades, the leaves varying from broadly oval to nearly orbicular, with very abrupt points. It grows from 9 inches to 1 foot in height. It flowers in May and June.

T. erectum var. *album* (*T. pendulum*) does not differ very much from *T. grandiflorum*; the petals, however, are invariably greenish tinted, sometimes yellowish; the leaves are also sharper pointed.

T. erectum var. *atropurpureum*, of which a good representation is given in the woodcut (fig. 47), is a much freer-flowering plant than any of the above two; the petals are of a dark mahogany colour, by which alone it is easily distinguished from *T. erectum*; they are inclined to droop. The leaves are less round, having a gradual taper to the point. This is a very desirable plant.

T. cernuum is more interesting than useful, as are also *T. sessile*, *T. nervosum*, and *T. discolor*, the latter being chiefly noteworthy owing to the large bright green, blotched, rhomboid leaves.—M. S.

SPRING TREATMENT OF CAMELLIAS.

So long as *Camellia* plants are in bloom little can be done to them towards preparing them for supplying flowers another year; but as soon as the last of the buds have expanded no time should be lost in taking them in hand to improve their condition. Many of the plants have now finished flowering, and others will be over very shortly. From the time the first flowers open until they are all over it is often difficult to syringe the plants without injuring the flowers, and some plants when left without attention of this kind are apt to become dirty. Sometimes a black matter takes possession of many of the leaves, and all the plants will become dust-stained on the foliage. To clean all such thoroughly before growth begins is one of the principal operations connected with the spring treatment of *Camellias*.

Established and healthy-growing plants do not often require any attention at the root. Plants in pots may have the drainage looked to without breaking the roots, and plants in beds and borders do occasionally require a little fresh soil by way of a top-dressing or extension of the rooting material, but this work should never be regarded as part of their annual requirements. It should be done thoroughly, and then no more will be wanted for years. *Camellia* roots must, however, be in good condition before leaves and blooms will form and expand properly. A compost of half peat and half loam, with a liberal dash of gritty sand added, is suitable for *Camellias*. Good drainage is also essential to success.

Where *Camellias* are growing luxuriantly they are very liable to become too close and thick. Two years ago we cut a cartload of superfluous branches out of our trees, and we are now dealing with them in the same way. Too many branches is as great a fault as having too few. An intricate mass of branches will never be well furnished with buds. Exposure to sun and air is necessary to form and mature these, and a judicious distribution of the wood is therefore requisite. Thinning should be done chiefly in the centres of the bushes. The small spindly twigs should be taken out first; these do no good as bloom-producers, and only stop the circulation of air. After these, all branches which cross or rest on each other are taken off, and the whole are thinned out in much the same way as we should treat an Apple tree when pruning it in winter.

In unfortunate cases where scale, mealy bug, and such pests are in possession a general syringing and brushing should be given with water heated to 90° and containing some insecticide. In ordinary cases of dirt sponging the foliage and a good syringing will suffice, and in many instances syringing alone will be enough.

The plants may next be started into growth. This is best done by having the roots in a moist state, and keeping them so. The branches should be syringed two or three times weekly; the atmosphere should be kept humid, and the temperature from 60° to 70°. Under these conditions substantial growth will be produced, and as the days lengthen and the weather brightens the wood and flower buds will gradually mature. *Camellias* may be had in full bloom eight months after the date of their beginning to make the young wood, and this information will be a guide for beginners who may want their *Camellias* in flower at a certain time.—M. M.

HOW I RAISED A GOOD SUPPLY OF PARSLEY.—Last June, finding I was short of my usual lot of Parsley, I at once put some seed in a pan with damp sand, and placing it in the stove to germinate, which it soon did. I then sowed it in a bed, and covered it with mats till I could see

the plants. These were carefully attended to till ready for transplanting. Inserted in well-prepared ground, they grew quickly and strongly and afforded a good supply of Parsley when most of my friends had none. The roots were dipped in soot water before insertion.—J. WINDSOR.

EAST LOTHIAN STOCKS—BEGONIA ROEZLII.

I READ with much pleasure in your number of the 6th inst. the article on the above subject because it gave me some hope of being able to recover a lost treasure. Some years ago I had some seed of East Lothian Stocks from a nurseryman in Scotland, whose name I have never been able to recall. I conclude that I applied to him in consequence of an advertisement I saw in the Journal. I sowed the seed in July, and when the plants were large enough to handle planted them three in a pot, and kept them during the winter in my orchard house. As soon as they showed the blooms I pulled out the single ones, gave them a shift, and placed them in alternate colours—white, purple, and scarlet, between my Peaches and Nectarines. They flowered magnificently, and anything more charming than the aspect of the orchard house with the Peaches and Nectarines in bloom, the Stocks occupying the intermediate spaces, and a few pots of Roses and Mignonette interspersed, can hardly be conceived. When the first bloom of the Stocks was over I had thought of removing them, but they had no intention of allowing their beauty to fade away so soon. They had rooted through into the border, and after being topped continued to yield an abundance of flowers for several months, so that the fragrance which had made the house so delightful when the trees were in bloom still pervaded it when I gathered the ripe fruit. I have sown East Lothian Stocks (so called) since, but with very different results. The reason of this has, I think, been satisfactorily explained by Mr. Campbell, and I hope I may once more obtain some true seeds.

BEGONIA ROEZLII.—Have any of your readers tried the Begonia Roezlii? To my taste it is one of the most elegant winter-blooming flowers we have. In a house kept at about 60° it begins to bloom early in February, and continues for several months, sending out its branches with clusters of terminal flowers of the most brilliant kind. It is of easy culture, and comes in well as the Poinsettias are passing away. I have plants 2 feet high, with branches of bloom to the number of eight or nine thrown out from every joint.—C. J.

WE learn that the next SPRING SHOW OF THE ROYAL HORTICULTURAL SOCIETY, to be held on the 25th inst., promises to be specially good. Hyacinths will be very strongly represented, and they are exceptionally good this year. Special prizes are also offered for Amaryllises. There will also be a fine display of Primroses and Cinerarias. As announced last week there will be a special exhibition of Daffodils on Tuesday, April 1st, and from the favourable season a most interesting exhibition is expected. A paper will be read by Mr. F. W. Burbidge at a meeting to be held at one o'clock, Professor Michael Foster, F.R.S., in the chair, when the principal English and continental cultivators of this charming flower are expected to be present.

— IT would appear that the qualities of CHIONODOXA LUCILLÆ as a garden plant are by no means generally known at present; it has been highly praised by some and denounced by others as no better than a Scilla of ordinary merit, but under good cultivation some extremely satisfactory results may be expected. We are credibly informed that in Dublin spikes have been produced by plants a foot high bearing "eleven flowers each, some of the bulbs being as large as a Hyacinth." If liberal treatment can insure such success there can be no question as to the position the Chionodoxa will soon attain in public opinion.

— THE decorative value of Messrs. Veitch's new species of DUMB-CANE, DIEFFENBACHIA JENMANI, will soon obtain a prominent place for it in all gardens where handsome variegated stove plants are appreciated, as it is one of the most distinct of all the numerous forms that have been introduced within recent years. The leaf is neat in shape, of a bright clear green colour, with oblong blotches or streaks of pure white parallel with the lateral veins, the contrast being most striking. It is of free growth, and will undoubtedly readily make large and imposing specimens.

— AFTER a singularly long and honoured service MR. MATHISON, gardener to His Grace the Duke of Buccleuch, Bowhill, Selkirkshire,

died on March 13th, aged ninety years. Until within the last few months Mr. Mathison attended regularly to his duties, and we believe him to have been the only gardener in Britain who, at the time of his death, remained in active service till his ninetieth year. He entered in the Duke's service at Bowhill about sixty years since. He was a man of splendid *physique*, and the same may be said of his stainless character, which led to his having been very much respected by his noble employers and by all who knew him. All honour to his name and memory.

— MR. JUSTUS CORDEROY writes:—"The very pretty early-flowering SAXIFRAGA CYMBALARIA seems but little known. I received it some years ago from Messrs. Backhouse of York. It is a very free-flowering and most accommodating plant; it can accommodate itself to any place; and when bearing its pretty little yellow flowers and shining foliage it is very attractive. It is dwarf or medium in growth; if on a dry wall it is very dwarf, about an inch high, but near the water edge it grows stronger or in the border; it is at home in the greenhouse, where I have seen it on a waterfall incased in ice. I have it now in a border under glass, about 1½ foot from a flue, under a north wall. It is an annual, sowing itself, and requires little attention."

— MR. C. WOLLEY DOD writes:—"On page 206 'X.' thinks that there is 'no basis at all' for the variety LEUCOIUM CARPATHICUM. He may be right, and in support of his view I may say that a hundred bulbs bought two years ago as Leucoium vernum produce flowers, some with green spots, some with yellow, and scapes some two-flowered, some one-flowered. Herbert, however, who has been thought a good authority says ('Amaryllidaceæ,' p. 331):—"I see no reason for confounding L. carpathicum ('Bot. Mag.' 45, 1993) (spathe, two-flowered; spots on the perianth yellow) with the one-flowered green-spotted vernum. I believe that vernum does not ever produce a two-flowered scape." (See 'Bot. Mag.' 2, 46, for L. vernum)."

— SPECIAL SOCIETIES.—Relative to the controversy on this subject which has recently appeared in our columns, we have received a communication from Mr. E. S. Dodwell, in which he complains that "Fair Play" "has grossly libelled him by name." We have authority from "Fair Play" to state that if Mr. Dodwell will point out wherein he considers himself aggrieved he will be happy to make the *amende*. We also feel ourselves aggrieved by the extraordinary letter signed "E. S. Dodwell," which appears in the *Gardeners' Magazine* of last week.

— MESSRS. J. CARTER & Co., High Holborn, send us examples of their EMPRESS POPPY ANEMONES, which are exceedingly fine, and merit the highest praise. The flowers are from 3 to 4 inches in diameter, of the richest and most varied colours—lilac-blue, violet-purple, intense crimson, bright carmine, red, blush, and white, most of the dark colours with a ring of white at the base, and all with a dense central tuft of black anthers. The sepals are of great substance, thick and lasting, and the plants are evidently very well and strongly grown.

— MR. R. P. BROTHERSTON sends us a BOX OF FLOWERS bright and beautiful, comprising the following:—Phalænopsis Schilleriana, a spike of eight flowers, much more richly coloured than is commonly seen, and of fine substance; Tea Roses, fresh, fragrant, and lovely, especially Madame Willermoz; Carnations, scarlet, white, and salmon, from plants that have been in flower for several months; Zonal Pelargoniums, scarlet, crimson, pink, and salmon, in trusses of twenty to twenty-four, some of the flowers exceeding 2 inches in diameter; Wallflowers, extremely dark in colour, and most fragrant; a charming silky purple Sisyrinchium grandiflorum, a large-flowered and deep purple variety of Aubrietia, somewhat like a fine Hendersoni; Dog's-tooth Violets, Pansies, with blue, white, and pink Hepaticas are all welcome indications of the advancing season, and arrived after their long journey as fresh as if but just cut. Mr. Brotherston considers nothing better as packing material than ordinary wadding, or "cotton wool" as it is termed, dry moss also being suitable; but these flowers are far the best that we have ever received packed in that moisture-absorbing substance.

— THAT superb Orchid ODONTOGLOSSUM PESCATOREI VEITCHIANUM continues unsurpassed in colouring amongst all the beautiful forms of the O. Alexandræ and O. Pescatorei type. Baron Schröder's unique plant at South Kensington last week had one panicle, with twenty-seven flowers of quite as good form and as richly coloured as on previous occasions. When Messrs. Veitch & Sons first showed this plant at Kensington, March 28th, 1882, it caused quite a sensation, as the spots

and bars are boldly marked, and of a distinct violet-purple colour on a pure white ground, the flowers also being very symmetrical. So handsome a variety was a suitable addition to the fine collection of varieties at The Dell, Egham, and Baron Schröder did well in securing it as a companion for his numerous valuable specimens. It may be incidentally mentioned that some growers have estimated this plant to be worth £250.

— CINERARIAS are now in excellent condition at Woodside, Farnham Royal, for Mr. James seems to have surpassed his previous efforts in the production of large substantial blooms and deep rich shades of colour. Some object to large flowers as coarse, but this cannot apply to the Woodside strain, for the utmost refinement is preserved, together with a velvety lustre of colour that renders the flowers very handsome.

— "B." sends us a box of *MAGNOLIA CONSPICUA* flowers as pure and wax-like as *Lapagerias*, and remarks:—"This is one of the most beautiful spring-flowering shrubs I know; its large white blooms well repay for what little attention is required at this time of the year to protect them from frost and cold winds. I have a large plant of it here with some hundreds of blooms just expanding, like those enclosed. The plant is perfectly hardy, having never been protected during any of the late severe winters."

— THE same correspondent observes:—"I am somewhat surprised to see Mr. Luckhurst calling *AZARA MICROPHYLLA* a climber. I have several plants of it, and find it quite a shrub. One plant stands out on the lawn here, about 6 feet high, quite a bush, being one of the first plants that Messrs. Veitch sent out. It has for several years flowered, and the berries have set freely, but I have never succeeded in getting any of the seeds to grow. I have propagated it from cuttings taken off the old plants in September, and inserted in a cold frame, have made good plants by the following autumn."

— THE local and general press have much to answer for in regard to the mis-rendering of PLANT NAMES, and instances of such are frequently brought to notice. One now before us in a report of a meeting at which a number of plants were employed refers to some well-known Palms as "*Latama Borbonica*," "*Kenthia Belmorenia*," and "*Corplyha Australis*," very moderate slips, but "*Robusta Arabia Reticulata*" is rather mystifying, and would seem to be a combination of *Grevillea robusta* and *Aralia reticulata*.

— WE are informed that "Messrs. Webb & Sons, the Queen's seedsmen, Wordsley, Stourbridge, offer valuable prizes for the best dish of their NEW PEA, THE WORDSLEY WONDER, to be competed for at the Royal Horticultural Society's Show, South Kensington, on July 22nd next."

— AT the last meeting of the Royal Horticultural Society PRIM-ROSES AND POLYANTHUSES were shown in strong force, and constituted the chief feature of the attractions. The Woking plants were exceedingly fine, the diversity of colours being surprising, from the richest crimson and purple blue to the most delicate mauve, lilac, yellow, and white, presenting a range of hues seen in few plants at this time of year. The profusion of flowers, too, renders them of great value for culture in pots. Mr. Waterer's plants had been lifted from the open borders as soon as the buds were showing, potted, and placed in a cool frame or house kept well ventilated, the principal object of this protection being to prevent heavy rains injuring the flowers and spoiling their appearance. They became established in a day or two, do not suffer in the slightest degree, and the flowers expand freely. For a conservatory or greenhouse stage such plants are most useful, and continue in flower for a week or two. The Polyanthus Prince of Wales, which was certificated, is probably the finest that was ever been shown both in size and colour. The individual flowers were 2 inches in diameter, the heads containing ten or a dozen each, and the colour a beautiful warm shade of crimson. One of Mr. Dean's varieties, named Blue Beard, was equally remarkable for the clear deep violet blue colour, much superior to any "blue" yet produced.

— WE have received a copy of the new issue of "CARTERS' PRACTICAL GARDENER," which has now reached the eleventh edition, bringing up the total sale to 81,000—a convincing result of its great popularity. It is a handy book of reference for amateur gardeners, and a safe guide on the culture of flowers, fruit, and vegetables, the various chapters having been written by some of the most successful gardeners of the day.

DIGGING.—I notice on page 184 that a correspondent advocates commencing digging at the lowest part of the piece of ground to be dug.

This may be the easiest way of getting the ground level, but it tends to reduce the depth of surface soil at the upper part. In the Hop gardens and fruit plantations here, which are dug annually, and the men are paid by piece-work, they always commence at the lower part and throw the soil downwards. In consequence, in the upper part of the gardens, the subsoil is quite close to the surface, and in the lower part there is a great depth of top soil. On my own ground those portions which I have dug at all are dug uphill, which keeps the depth of soil more even and counteracts the tendency of the soil always to move downhill when hoed, or by the action of rain, &c.—W. K., Maidstone.

PRUNING ROSES.

"EXPERIENTIA DOCET" and "D., Deal," will doubtless by their timely remarks on this subject relieve the minds of young Rose-growers who are watching Rose growth anxiously, if they have not already been induced to prune their plants. If they have not used the knife they will be encouraged to wait. Each year I watch I become more convinced that the later the pruning the better for the blooming season, and in cold districts much exposed to the delightful (?) bracing period of nor'-nor'-easters this is more than ordinarily necessary.

"Experientia Docet" does not, however, mention what I fancy most growers imagine injures the plants that are cut back when in this advanced state of growth, when, as he remarks, the bud can be detected at the end of the shoots—viz., the bleeding or weeping, which, if growing weather follow the pruning, is pretty certain to be seen. This weeping, many imagine, must weaken the plants. I do not think it does; at least, I know that beautiful blooms may be obtained from plants that have bled freely. I do not care to venture on any theories about sap. All I know is that good blooms have followed on these plants that have bled freely so as to damp the soil after being pruned. Would these blooms have been ever so much grander had the plants not bled at the section? Who can tell? Supposing the plants pruned earlier no bleeding would take place, but the sap that would have flowed in the later pruning, must, I presume, be rising now and pushing forward the lower buds into succulent growth, the very growth that is certain to suffer from late frosts. It seems to me it is a choice of two evils, and as the old saying advises us under such circumstances to "choose the least," I confess to believing that the least is the late pruning.

Somewhat connected with this subject is the protection given to our Roses during the winter. I doubt not where there are plenty of hands this may be done by covering only when severe frost comes, and uncovering again. There is no question to my mind that during the past winter it was wholly unnecessary, in fact I wish I had not done it; but my man Friday cannot dance attendance on Roses only, and I must get them into winter quarters in early December, and my plan is to cover with bracken and long coarse grass. There is evil as well as good in this with such a winter as we have had. I think there is a degree of heat in the moistened Fern fronds which stimulates growth in the lower buds and disposes some of them to start sooner than is desired, and this is approaching the same effect that the early pruning has. I think it is wiser to uncover early in March. Even then with the last two winters lovely coloured pink shoots will be showing from the root, and are likely to suffer from late frosts. Last winter in March we had for several nights over 20° of frost, and my winter clothing was all in a heap decaying. I confess I looked with some anxiety for the result. Not a few of these pink-root shoots were cut down, but I never grew better Roses; and the few times I ventured into the exhibition tent a fair share of success awaited me, and until sadder experiences attend me it will be my plan of action to uncover early in March. If the winter have been unusually severe and prolonged it might be the exception.—Y. B. A. Z.

ORTHOSIPHON STAMINEUS.

THIS is a very pretty and interesting member of the Labiatae, and is well deserving the attention of growers of stove plants; for, coming into full bloom about the end of July, it becomes extremely valuable in a decorative point of view, serving to enliven the plant stove just at the time when there is somewhat of a dearth. As a genus, *Orthosiphon* is closely allied to *Ocimum*, *Coleus*, and *Plectranthus*, but its inflorescence reminds one of a *Clerodendron*.

Orthosiphon stamineus is herbaceous in habit, and forms neat little bushes, which if required may be had in bloom when only about 6 inches high. Most cultivators will, however, prefer growing it to a larger size before allowing it to flower, and, therefore, when any bloom buds which are not required to develop make their appearance, they must be picked off. The stems and branches of this elegant little plant are furnished with light purple hairs; leaves sharply oval, toothed on the edges, and dark green on the upper side, but glaucous beneath, the veins in addition being sparingly clothed with short white hairs. The flowers are produced in terminal racemes, as the illustration shows. The corolla is about an inch in length, bluish-lilac in colour, having the stamens much exserted, which adds materially to the beauty of the raceme.

The culture of *Orthosiphon stamineus* is really of the simplest nature, which is another feature in its favour, inasmuch as any amateur possessing a cool stove may take it in hand without the slightest risk or fear of failure. Drain the pots well; for soil use about equal parts of peat, loam, and good leaf mould, adding a little sharp river or silver sand to the whole so as to make it feel gritty when taken in the hand, and during the growing and flowering season supply the plant liberally with water. It appears to be widely distributed over India and through the islands of the Indian Archipelago, but was introduced to our collections from the neighbourhood of Cape York in north-east Australia, by the late Mr. J. G. Veitch.—E. C.

CULTURAL NOTES ON GREENHOUSE PLANTS.

LAPAGERIA ROSEA.—This excellent evergreen plant does not find a place in so many greenhouses as it ought to do. It can scarcely be considered difficult to grow. The price is also reasonable, and why not give it a trial. Procure a young healthy plant (the present

best place. It is planted out in a well-prepared border, consisting of good loam. With good drainage it grows like a Willow. Train it to a wire underneath a rafter. After it has grown say from 4 to 6 feet pinch it, when it will then throw out its laterals the later where the flowers will appear. When it has flowered we prune it on the spur system, and it will soon break afresh. Keep it securely tied, pinching any of the laterals that appear to be growing in advance of the others to balance the growth. Red spider appears to be its worst enemy amongst insects. It should be syringed daily when growing. A handful of sulphur to a canful of water occasionally keeps the spider at bay, and fumigate when in flower. Along with this I send a flowering lateral branch for your inspection.

HABROTHAMNUS ELEGANS.—This plant is well named elegans, with its beautiful carmine clusters of flowers. There is no plant better adapted for the back wall in the greenhouse than the above, as it does not appear to thrive in the full blaze of the sun. Some gardeners are prejudiced against it, as it is subject to attacks of

Fig. 48.—*ORTHOSIPHON STAMINEUS*.

is a good time to get one), repot it at once, using a mixture of good peat and loam, with as much fibre in it as possible, with a sprinkling of coarse silver sand, add also a little charcoal to keep the compost sweet. Do not overpot it. The drainage must be good, as it requires plenty of water after it has fairly commenced growing. There are various ways of training this plant. We have tried it on the back wall of a greenhouse, on wires underneath a rafter, and so on, but prefer the balloon for two reasons—namely, it can be easily removed from one place to another; when it is growing it appears to thrive better in a rather cool shady situation, and of course when in flower we like to see it in a more prominent place. It is easily kept clean by applying the syringe when growing; when in flower carefully sponge it.

CLIANTHUS PUNICEUS.—A very beautiful plant, but it has another recommendation besides being beautiful, for it flowers at a time when flowers are most appreciated—*i.e.*, in early spring. I once had a plant under my charge where it was trained in a span-roofed conservatory up one side of the house and down the other. A large white *Camellia* was growing underneath it. They both flowered at the same time, and the effect was magnificent. A plant here is trained somewhat similarly to the one mentioned. It is treated like a Vine, except in regard to temperature, the greenhouse being the

aphides, but any greenhouse plant is liable to these pests if not properly treated. Cleanliness ought to be the first consideration, such as the back wall of the greenhouse being whitewashed in the ordinary way, as well as the wires whereon it is trained. Plant it out as advised for the *Clianthus*. Make certain that drainage is good, as it is scarcely possible to overwater a vigorous-growing plant with perfect drainage. This is the secret of keeping it free from insects. As soon as it has done flowering prune at once, cutting out as much old wood as possible, replacing it with some of the strongest shoots that have just flowered. Do not train the young growth too closely. As soon as the flowers can be recognised stop tying it in; the weight of the flowers causes the branches to droop, which takes away the stiff formal appearance it otherwise would have.—J. J. C.

[The lateral branch of *Clianthus puniceus* sent by our correspondent was nearly 3 feet long, with vigorous healthy leaves 6 to 7 inches in length. There were twenty trusses of flowers and buds in different stages, one being produced from the axil of every leaf. It was one of the best grown examples of this plant that we have seen.]

BANKSIA ROSE BLOOMS.—The footnote to my remarks on this subject has at least explained what the writer meant by his directions on pruning

these in your issue of February 21st. Had he said all strong growth of one or two yards in length there certainly would have been little occasion for my questioning the value of the practice enforced. In self-defence I am bound to remind him that he said nothing about unripened wood except as regards the points of shoots in that condition, which he says should be removed; but in using the words "throughout the *strong growths*" (the italics are mine) the novice would certainly consider the 10 and 12 feet long shoots the strong shoots, not those of 4 or 5 feet long.—Y. B. A. Z.

A HYBRID FROM RHODODENDRON AUCKLANDI.

THE figure represents a flower and leaf (reduced in size) of a fine hybrid Rhododendron as above, raised by me. The pollen parent

the characteristics of *R. Aucklandi*, I have crossed similar hybrids to the one here figured with the pollen of the male parent again, and have a fine batch of seedlings two years old; indeed I have used the pollen of *R. Aucklandi* very largely in many experiments, which time will test.

The plant on which the flower here figured grew was 2 feet high and six years old.—J. H. MANGLES, *Valwood, Haslemere*.

AMARYLLISES AT CHELSEA.

THE annual exhibition of Amaryllises in Messrs. Veitch & Sons' nursery at Chelsea is now looked for by horticulturists as one of the standing attractions of the spring season, and large numbers of visitors will make a journey there within the next week or two, for these plants are most deservedly gaining great favour as their qualities are becoming known. For brilliance of colour and magnificence of effect they are unexcelled; and though few can hope to have such an extensive display as that at Chelsea, yet a dozen or two plants are invaluable at this time of year either in the stove or conservatory. In the Veitchian Amaryllis house there are now about 1200 spikes bearing from two to four open flowers or buds, and in a few days these will be at their best, as this bright warm weather is bringing them forward fast. Dazzling shades of scarlet are numerous, while the rich crimson tints serve to soften the effect considerably.

All the plants are plunged in tan to the rim of the pots; but until after the flowering time water is not too liberally supplied, as keeping the paths and plunging material moist is found sufficient, and preferable to drenching the soil. A temperature as near 60° as possible is maintained night and day, and if with sun heat it rises above this the ventilators are opened freely, providing the wind is not too keen; a little shade being also requisite. In the matter of soil liberal treatment has proved the best. A compost of good turfy loam with plenty of sand to keep it open, and one-fourth of old cow manure, is employed, the bulbs being potted in January and plunged, as mentioned above, no bottom heat being needed. After the flowers have faded the growth is encouraged by more liberal supplies of water both at the roots and over the foliage, the object being to obtain vigorous and well-ripened leaves and bulbs to insure satisfactory flowering in the following season. The plants are freely exposed to the sun as the growth becomes matured, and then rested until the starting time arrives again. At no period is liquid manure employed, as this has been proved to be less beneficial than a good proportion of stimulant in the soil, and the great point is to render the bulbs stout and ripe, as upon that in a large measure the quality of the flowers depends. Of course, this is influenced greatly by the character of the variety, but the best variety neglected in this matter will give unsatisfactory results.

The number of seedlings annually raised at Chelsea have added some scores of grand varieties to those already named, and in one house there are now five thousand seedlings, the results of last season's crossing. In from three to four years they produce flowers, and continue doing so each year until they reach considerable age, their capacity for flowering being apparently unimpaired. Every season we have the pleasure of announcing some novelties of sterling merit from this establishment, and the present season is no exception to the rule. One batch is very interesting, comprising the following:—General Gordon, Corsair, Canobil, William Goldring, Ceres, and Enchantress—all good varieties, and, strangely enough, from one pod of seed, the produce of a cross between Horace (the seed-bearing parent) and Auber as the pollen parent. These are of excellent quality, and will certainly gain much popularity.

General Gordon.—This is a bold and handsome variety with flowers 7 inches in diameter, the outer petals 3 inches in diameter and rounded. The colour is a bright reddish-crimson with a white central stripe extending to half the length of the petals. The spike is very stout and bears four flowers. This variety was certificated at the last meeting of the Royal Horticultural Society.

Ceres.—Very beautiful, the flower large and well formed, the petals broad and rounded; deep crimson, with a broad white central stripe. It is strong with six flowers in a head.

William Goldring.—Bold and effective, the flowers 7 inches in diameter; dark scarlet, with a central white stripe. Four in a head. This flowered last year, but it seems to have improved greatly.

Enchantress.—Flower handsomely formed, with broad rounded petals streaked with rosy crimson on a white ground. Four flowers in a head. Canobil is a neatly formed flower of a rosy tinge; and Corsair, rich scarlet, have been seen before; both are good. Of other new varieties he following are remarkable for their size and colour.

Ne Plus Ultra.—A magnificent variety, one of the finest that has yet been produced. Brilliant scarlet in colour, the flowers nearly 8 inches in diameter, the petals 3½ inches broad and of great substance. This was certificated at the last Kensington meeting.

Terence.—One of the large-flowered type, the blooms being over 7 inches in diameter, of a clear bright scarlet colour.

Fig. 49.—Hybrid Rhododendron Aucklandi.

was *R. Aucklandi*, the seed-bearer one of the common hardy hybrids. The floret was 3 inches across, and the truss contained twelve flowers. In colour the seedling was intermediate between the two parents, of a soft pink, paler in the centre, saucer-like in shape, and with small stamens after the manner of *R. Aucklandi*. The Editor of this Journal expressed great admiration of the flower; but it is not quite up to the standard of what I expect from some of my very numerous seedlings of this strain, which ought, I think, to yield a crimson equivalent of the male parent, one of the grandest and most beautiful of all Rhododendrons. For the purpose of raising a hardier strain with all

Minerva.—An imposing variety; flowers rosy crimson, 8 inches in diameter. Four in a head. Bold and rich in colour.

Brutus.—Very neat flower; bright scarlet, and vigorous in habit.

Pickwick.—A strong and free-flowering variety, with two spikes, each having three flowers; crimson streaked and netted on a white ground.

Bayard.—Intense scarlet; the outer petals tipped with white, which affords a striking contrast. The plant has two spikes and two flowers each.

Clarinda.—A well-formed flower, very delicate and pretty. The petals are white, the upper ones tinged with red.

Pollentia.—Of great size and substance; 8 inches across; rich bright crimson, fine warm colour, and with a very narrow margin of white.

Many other varieties are advancing, and will be noted as they develop their characters.

PRIMULA HARBINGER IN POTS.

MR. ABBEY (page 202) is right in his estimate of this beautiful hardy Primrose, grown as it is produced at Burghley and flowered in pots under glass. For conservatory and greenhouse decoration it is at the least equally effective with the best Chinese Primulas, and in the estimation of not a few surpasses them by its simple, yet massive, beauty. Harbinger is more of a Polyanthus than a Primrose. Its flowers are much larger than those of the common Primrose, also rounder, smoother, and nearly white; while they are borne in huge bunches, larger, and looser than ordinary Polyanthus. No doubt the plant is quite hardy, and will grow and flower freely in the open air; but flowers exposed to the wind and rain must necessarily be deficient in size, form, and purity as compared with those on plants having the shelter of glass. A cool, light, well ventilated house is a suitable position for Harbinger, or a frame from which frost is excluded will answer well. Crowded amongst other plants, far from the glass in a rather warm house, it would probably not be satisfactory. Planted out in rich soil in a shaded position in the summer and potted in the autumn would presumably be a successful mode of treatment, and certainly so easy that no one having even a small greenhouse need not deny himself the pleasure of growing this very attractive spring-flowering plant.—TRAVELLER.

NOTES FROM MY GARDEN IN 1884.

GLADIOLUS.

"THE whirligig of time" seems to turn more rapidly as we get older. It may be that the consciousness that there are not many more rounds of the clock for us to observe makes it appear to do so; but certain it is that time does seem to move more rapidly, and I can hardly believe that I have again to record the successes and failures of another year. Yet so it is; and as the time for dealing with the Gladiolus is now at hand I cannot do better than record my experience with this most noble yet puzzling flower.

Notwithstanding the opposition which was shown to my theory that the cause of such frequent failures and so many losses in their culture was purely and simply disease, and that no theory of bad culture or degeneration could account for it, I find that it is now beginning to be generally acknowledged, though I am not as yet prepared to admit that it is contagious. Various reasons have been assigned for this disease, which is certainly more prevalent in England than on the continent as far as my experience goes; but I do not think that it is very difficult to account for. Soil itself seems to make no difference. I say itself, but soil combined with climate certainly has much to do with their successful culture.

The present innumerable hosts of named varieties are the product, I believe, of two or three species—*floribundus*, *natalensis*, and *oppositiflorus*. *Gandavensis* and *branchleyensis*, which have been largely used in hybridising, are, I believe, garden hybrids. Now these parent species are natives of Natal and Madagascar, and hence they have the very different climate of these islands to contend with, more especially as to the ripening of the corms. It is well known that after the flowering time is over long herbage covers the ground, and then comes a hot scorching time, when the corms become thoroughly matured, the foliage having all withered away. Contrast this with our ripening time. Defer it as much as we will, we can never take up the corms before the foliage has died down, consequently they must lose the force it would otherwise acquire from the decaying stem, and weakness is thereby engendered; moreover, the high breeding of some of the varieties makes them more susceptible. In stating all this, I do not in the least profess to write scientifically, but I am not a bit frightened by that; and when I see what is now written on the subject of glazed *v.* unglazed pots I cannot suppress a smile at the utter dogmatism of scientific men. Why, there was nothing more impressed upon us in pot culture than that we must have pots as porous as possible, for, in the words of an American writer in "Harper's," "the roots need a circulation of air and the free exhalation of moisture as truly as the leaves;" and yet such scientific gardeners as Mr. Thomson of Drumlanrig advocate their extensive use. However, this by the way. I may be wrong in my science, but I think common sense is on my side, and that the disease is no way unaccountable. The comparative freedom of the French growers from this disease is due, I think to their climate, and more especially to their finer and drier autumns. An autumn which will ripen the Chasselas de Fontainebleau Grape in the open is very different from ours; and, although they lose their roots, they do not do so to anything like the same extent that we

do. For the same reason I should imagine that they would do well in some of the eastern States of North America.

And now to my own collection, which does not exceed, including seedlings, some 500 or 600 corms. I had one large bed 33 feet long of French-grown roots; another of nearly the same length of my own harvesting, containing also a few of Mr. Kelway's varieties; a bed of seedlings, and a small nursery of young corms saved from those of the previous year, generally known as spawn. I did not last year take the same trouble in planting that I had done—namely, making a hole for each bulb, but contented myself with drawing drills and planting them in the rows. I was quite satisfied with the result, and certainly never had a more healthy-looking or vigorous bed than that of the French varieties. They every one came up. All threw up spikes of bloom, some of them magnificent, but—then disease began to manifest itself, the foliage turned brown, and I suppose quite one-fourth of them were useless. My own harvested corms were not so good: I had some fine, but also some weakly spikes, and I suppose I lost fully one-third of these. The seedlings, as is the way of youth, were vigorous and strong; but even amongst these there were diseased roots, which had to be thrown away. The cormlets or spawn had increased in size, and some of them will, I hope, bloom next year. I did not top-dress this year with manure as I had previously done, but with cocoa-nut fibre, so as to prevent evaporation, and the character of the season was such that I had not occasion to water the beds once. One of the most curious facts that I observed was this: it is now ten years or more since I planted some where I now have my Roses. As is always the case in taking up, some cormlets are knocked off in harvesting. Every year some of these have made their appearance, and have often fair good spikes of bloom; but this year one, which was evidently *Antigone*, threw up three splendid spikes, and I harvested three sound corms. It will be remembered that during this time we have had the two severest winters of late years, and the series of wet and unfavourable seasons culminating in 1879, and yet they flourished all through these seasons. This might suggest the leaving them in the ground all the year, but a trial I once made of this did not encourage me to try it again. It is one of those things which "no fellow can understand." I have noticed also again this year that a plant which has thrown up two stems and formed two fresh corms, one of them has been diseased and the other sound. Just as with Potatoes; you will find on the same haulm some utterly bad and others perfectly sound, while seedlings that have never bloomed also oftentimes decay and are lost.

Taking these things into account I must still hold that the growing of the Gladiolus is a perfect lottery. I have seen and heard of most of the collections grown in this country, and the only person who seems to me to be thoroughly successful is "W. J. M." of Clonmel; and yet, knowing the rainy character of the Emerald Isle, I should not have thought it favourable. I know how many growers have suffered there, and thereby "W. J. M." is exceptionally fortunate. He attributes a great deal of his success to storing; but if a corm is sound when lifted it keeps so, if unsound nothing will cure it.

I have before alluded to the cutting the corms previous to planting, so as to increase the stock. I did so again last year, and found that some of the largest were those formed on the cut corms. I would, therefore, advise all intending planters to examine them, taking off the outer jacket, and, when two fresh eyes are observed, cutting the corm in two, so as to secure one for each piece, precisely as would be done in the case of a Potato; and in the case of new or scarce varieties it commends itself especially to those who cannot afford to purchase more than one bulb of a sort.

As to varieties, I have lately given a list to a relative who wanted to order some, and it is astonishing, in looking through the list of French sorts, how few come up to the standard of excellence one has set. I give the list:—Baroness Burdett Coutts, Rayon d'Or, Murillo, Horace Vernet, Archduchess Marie, Christine, Shakespeare, Madame Desportes, Le Vesuve, Dalila, Jupiter, Africain, Flamingo, Norma, Pasquin, Caprice, De Merbel, Victor Jacqueminot, Flamboyant, Opale, Comice, Mdile. Marie Verdalle, Madame Marie Mies, De Lesseps, Mabel, Mount Etna, Eclair. Of those of in 1882 and 1883 the following are, I think, the best:—

ABRICOTE.—Very fresh apricot colour, lightly shaded with lilac; somewhat late in flowering, vigorous and hardy.

ARABI PACHA.—Very lively scarlet, with large white spot.

GRAND ROUGE.—Splendid spike of scarlet-red flowers with small violet spot. A magnificent and effective plant.

NEREIDE.—Long and close spike, large, of a shaded rose colour. Magnificent and delicately coloured plant.

It is with no disparagement of Mr. Kelway's flowers that I have not enumerated any of his, but in truth I know but little of them. Duchess of Edinburgh is a grand but very late flower. Lady Bridport is a good useful exhibition flower. But his varieties are so numerous that one gets bewildered amongst them, and the varieties brought out last season were probably exhibited some six or seven years ago. I have only written of that which I know.—D., Deal.

NOTES ON SARRACENIAS.

THE present time is the proper one for repotting these plants preparatory to their being placed in a warm house to make their growth. If the plants are healthy and strong, and the compost in which they were planted last year is in good condition, a top-dressing of fibry peat and sphagnum moss will be sufficient for them this year. In most cases, however, it will be found that the effect of copious and

frequent supplies of water during the whole of last year has been to decompose the soil and make it unfit for the plants to remain in it a second year. Should it be decided to repot them it will be found a good plan to turn the plants out of the pots and immerse the ball in a tub of water, the effect of which is to loosen the soil, which, by rubbing it gently with the hands, is readily removed from the thread-like roots. Unless this is done it will be difficult to shake the plants out of the old soil without breaking off a large number of roots, thereby running the risk of weakening the plants. Although many cultivators prefer to leave the old leaves and pitchers on the plants until the new growth is made, it is a good practice to cut away all shabby leaves, leaving one or two of the best to each crown.

For compost peat in small pieces, with a portion of the small matter shaken out, sphagnum moss, and crock dust form a mixture such as *Sarracenia* delight to root in. Either pots or pans may be used, half filling them with drainage. As the *Sarracenia* are surface-rooting plants it is necessary that the pots or pans in which they are to grow should be sufficiently large to afford room for the roots to ramify freely near the surface of the soil. The crowns should be planted just level with the surface, and the mixture pressed in firmly. Apply water liberally when the potting is completed. A position near the glass, in a house with an aspect which will catch the sunlight all day, and where the temperature can be kept above 50° during cold spring nights, are the requirements of *Sarracenia* during their growing season. It will be unnecessary to ventilate unless the temperature of the house rises above 80° with sun heat; for although these plants do not like fire heat, the heat of the sun is necessary to their making large well-coloured pitchers.

The syringe should be used twice or thrice daily, and a good saturation with tepid water at the roots should be given every morning, *Sarracenia* being almost aquatic in their habits, and therefore requiring frequent waterings at the roots. Never mind about the plants being wet, the water is required all the same. As the pitchers ripen a weak solution of cow dung is useful in assisting their development and colouring. When growth is completed more air may be given. Cold draughts, however, must be carefully avoided, or the pitchers will soon suffer. Green fly attacks these plants, especially during the infancy of the pitchers; and as much harm is done by even very few of these pests, it is a good plan to fumigate the plants with tobacco smoke about every fortnight. *Darlingtonia* may be successfully treated as advised for the *Sarracenia*.—W. W.

POSTAL BOXES.

THE magnitude of the trade in plants now conducted through the parcel post, and the commendable custom that has increased so rapidly of late, has excited the ingenuity of manufacturers in producing boxes of various sizes for the purpose in question. Samples of some of these boxes are before us. The first received was the "unique" folding box of Mr. Thomas P. Bethell of Liverpool. This is made of cardboard, and can be flattened out and prepared in a moment in the form of a box rigid and

Fig. 50.

secure. This is the lightest of all, but the larger sizes especially are not sufficiently strong for rough usage.

The Patent Package Company, Fenchurch Street, London, sent us a sample of a wooden box, strong, yet not heavy, simple and effectual for the purpose for which it is made.

Fig. 51.

The Collapsible Packing-case Company, Weybridge, manufacture their boxes of tin on the ground that they thus possess strength, lightness, portability, security, and economy, and the example before us shows that their claim is well founded. The boxes when open

(fig. 50) can be packed away like so many sheets of tin, while when closed (fig. 51) they form fitting receptacles for plants and flowers.

ABUTILONS IN SMALL POTS.

MUCH can be done with the *Abutilon* with but very little trouble. We have plants raised from seed sown last spring, which have made remarkable growth in 5-inch pots, being now fully 3 feet in height, some furnished to within 9 inches of the pot and about 18 inches through. These plants have been in flower since the first week in November, and are now showing scores of flowers, in some instances two on a stalk.

They have been grown in a temperature of about 55° by day and 50° at night, allowing more with sun heat, which we have had but very little of since November; the soil used was good mellow loam. They have also

received good supplies of Clay's fertiliser, in which they evidently delight. The plants have been kept in saucers since they became root-bound, as, if the roots are allowed to become dry, the plants will be sure to lose their foliage and flower buds also. The seed was obtained from Messrs. Cannell of Swanley, and some of the seedlings are very good indeed, especially a pale primrose, which is very prolific.

I purpose giving the plants a good shift and growing them outside during the summer months, not allowing them to flower till the autumn, when I expect them to be useful for the winter months.—J. P., *Summerhill*.

PLANTS AND FLOWERS OF THE PAST AND PRESENT.

LOOKING over an old copy of the "Scottish Gardener" to-day I was much struck with the difference of plants then cultivated compared with those which now adorn our hothouses. This difference was most vividly brought to my mind on examining the prize list of the Caledonian Horticultural Society's Show for the year 1857. Among the plants comprised in the winning collections of stove and greenhouse plants were the following:—*Leschenaultia formosa*, *Pimelea spectabilis*, *Pultenaea stricta*, *Calceolaria violacea*, *Podolobium triangulare*, *Mahernia incisa*, *Tetratheca verticillata*, and many others which it is needless to enumerate. Amongst Cape Heaths I also noticed a good many strange names. The same may also be said about Pansies, Dahlias, and several other florists' flowers. In fact, among the twelve varieties which composed the first-prize lot of Pansies I did not recognise one familiar name. I do not wonder so much at the changes which have taken place amongst florists' flowers, but what has become of the good old hardwooded occupants of the stove or greenhouse, the successful cultivation of which was, I understand, the gauge by which a gardener's abilities were measured? Has the advance of horticulture and floriculture given birth to better and more useful varieties, so that the older sorts have had to yield to the rule of survival of the fittest, or have they become the victims of popular taste, by which the more showy and easier cultivated softwooded plants have gained the day? I know that occasionally these old favourites are to be met with, but only in some secluded spot where such things are carefully looked after and treasured as relics of the good old days. Doubtless there are many readers of the *Journal* who can look back to the days when such plants as those I have named were popular everywhere, and who have watched, perhaps sadly, the gradual encroachment of the modern usurpers, if I may use the term. Mayhap some of them will be able to tell us if, after all the progress that has been made in gardening, any improvement has been made in this branch of it.—CALEDONIAN.

SPORT'S PHYSIOLOGICALLY CONSIDERED.

THE following paper was read by Mr. J. W. Talbot last year before the Massachusetts Horticultural Society, and is published in the last part of their Transactions.

"To call a natural phenomenon a *sport*, is to admit our ignorance of the natural laws by which it was produced. To be satisfied with that term evinces a willingness to remain ignorant. But such phenomena are very common. When, for instance, a branch upon the stock of a Rose, or any other shrub or plant, produces a blossom essentially different from the others, it is called a sport. When, in grafting, the result is different from what we had reason to expect, we call it sporting. When the green-leaved Laburnum was budded with the golden, and the shoots below the bud, and even those from the roots were variegated, the new variety thus obtained was called a sport. So, when the yellow-striped Jessamine was grafted on the white, and the smaller-leaved Abutilon was grafted on the larger-leaved, the two new varieties thus obtained were called sports. When, in Amherst, N.H., a large Baldwin tree, originally grafted near the ground on a Russet stock, threw out a shoot 20 feet above the graft, bearing Apples that seemed to be a cross between the Baldwin and Russet, it was called Whiting's Sport, after the owner. Tradition tells us that more than a century ago buds of the Golden Sweet and Rhode Island Greening, being split and their halves united, produced the well-known Apple, one side of which is sweet and the other sour. This Apple has always been called a sport. These are a few of a large class of phenomena which, appearing to be contrary to natural laws, have been called sports. The term, however, is an unfortunate one. Nature never sports. All her laws are immutable. It is only when we cannot comprehend that she appears to sport.

"Cases like the above, connected with grafting, cross-fertilising, or hybridising, will never be perfectly understood until men better understand the laws of vegetable anatomy and physiology. The advance made in this direction within a few years has already explained many of the mysteries of former times; and is it not reasonable to expect that scientific men, availing themselves of past discoveries, with the improved apparatus and opportunities of the present, will soon be able to trace what are now called sports to natural causes? But let us bear in mind that the practical man, who carefully observes and records natural phenomena, may be the scientific man, whatever he may be called.

"The better to learn the origin and understand the nature of sports I wish to call your attention to a few familiar but well-established physiological facts and truths. It is not long since the most absurd and contradictory views prevailed in regard to the circulation of the sap. That most trees and plants derive a large part of their nourishment from the soil will not be questioned. Nearly all writers of note now admit that the crude sap ascends from the roots, through the sap wood, to the upper side of the leaves, where it is elaborated by coming in contact with the air, exhaling the superfluous water and oxygen, and inhaling carbonic acid. It then passes into the veins on the under side of the leaves, to be conducted into the chlorophyl vessels in the bark, where it is digested and assimilated on its way into the cambium, where it forms the protoplasm or life principle which

circulates to every part of the plant, much as the blood circulates in the animal system. So well are botanists and physiologists agreed upon this subject that controversy has nearly ceased. From this we obtain an idea of the source of the protoplasm, which originates not only all sports but all growth in plant life.

"Another class of well-established facts which we must understand before we approach the subject of sports relates to the cell structure of plants. All plants originate in, and are composed of, minute cells. Every natural plant or tree came from one parent cell, which had the power of multiplying itself and building up the whole plant or tree. From every parent cell in a plant or tree, whether in root, branch, bud, or leaf, may be developed another branch or tree, which will be true to its kind. No natural plant or tree can of itself alone ever change its kind. On this fact depends the permanency of varieties. Keeping these facts in mind, we will now consider the formation of the cells. All writers admit that every cell is formed in the cambium by the protoplasm. According to their description, the protoplasm is one of the most wonderful agents in the world. They assure us that it has an inherent power of motion as persistent and independent as the beating of the heart, and even more so, for, while the heart is always confined to the same relative spot, the protoplasm changes its locality and performs various kinds of motions, and seems to be endowed with a wisdom to foresee and plan, and a skill to execute the most varied operations. It not only forms the cells, but changes their forms to make tubes and vessels, woody fibre, bark, buds and leaves; secretes the gum, starch, sugar, and all the materials that enter into the composition of plants; produces the most delicate blossoms, the most delicious fruits, and finally, to perpetuate its kind, inserts in every specimen of fruit a little embryo of itself in the well-protected seed. All this is ascribed to the protoplasm. Men witnessing this wonderful display of wisdom and skill everywhere seen have called it Nature, and bowed in reverence; but let us rather view it as the handiwork of the Infinite One, whose wisdom designed, whose power executes and upholds, and whose boundless love pervades the whole. Or with the poet, exclaim,—

'All are but parts of one stupendous whole,
Whose body Nature is, and God the soul.'

"But that protoplasm is the agent by which all vegetable growth is carried on must be admitted. By the improved microscope we can actually witness the wonderful process. We can see the first step toward the formation of a cell. We can see the protoplasm in the cambium, as it forms itself into a little globe or ball to become the nucleus of the future cell. We can see it begin to rotate and take form, as it secretes the substance with which it surrounds itself with a cell wall as perfect as the shell of an egg. Thus the nucleus, the cell sap, and the cell wall constitute a parent cell. The nucleus is simply living protoplasm, which, as soon as the first cell is completed, divides itself into two parts, each taking an end of the cell, begins its rotary motion, divides the cell wall, and from the half each forms a new cell as perfect as the first. Thus from one cell two are formed, each to be again divided, and thus on to infinity. But when a sufficient number of cells are formed, one above another, a new work commences, with which we are particularly interested. The protoplasm in the perpendicular row of cells begins to absorb the transverse septa or end walls which are in contact with each other; and joining the side walls together forms tubes or sap vessels; then, passes up through the tubes thus formed and uniting, recommences its work of cell-building to complete the plant or tree. It is the union of the protoplasm or the contents of these cells as it absorbs the cell walls between them and recommences cell-building, that gives the key to the origin of sports."

(To be continued.)

THE INSECT ENEMIES OF OUR GARDEN CROPS. THE CHERRY.

THOUGH not prepared to give statistics in the matter, I venture to assert that the production of British Cherries has hardly increased of late so as to rival the production of other fruits which are in greater demand than formerly, owing to the growth of our population. I do not mean to say that the attack made upon the Cherry by some medical authorities on the plea of its unwholesome nature has had any notable influence; it is rather the effect of a considerable importation of this fruit from the continent. Then, again, our Cherry orchards have suffered very much in recent years through unfavourable springs; and in Kent, doubtless also elsewhere, much damage has been done by the severe gales we have had since 1878, many old but good-bearing trees being uprooted or losing some of their branches. With regard to the insect foes of the Cherry, the reports published do not show that they usually cause any great loss of fruit. They are, however, somewhat pertinacious, and in 1872 and 1873 no little stir was occasioned by the appearance and abundance of the "slugworm," a creature that is one of those insects which have naturally a repulsiveness about them.

We have accused America of sending us a blight, that all our efforts cannot entirely free our Apple trunks; also, and for years past, we have been in fear that the American Potato beetle will yet make a settlement here, and some persons have also been very positive that the "slugworm" came somehow across the Atlantic about ten or twelve years ago. It is true that the best account given of it was written by Prof. Peck at the close of last century, and published in Boston, U.S., but the insect (or some of them, for there are various species) was known in Europe long before then. Fabricius, Reaumur, and Linneus all observed these slimy larvæ of sawflies, though in some respects

they mis-stated their habits and history. Even now we are doubtful as to the specific boundaries. The late Edward Newman, for instance, thought that under the general name of *Selandria æthiops* (figs. 52 and 53) might be included the various larvæ observed in the Pear, Sloe, Plum, Cherry, and other fruit trees. It is certain, however, the species are more numerous than he supposed. Thus the Cherry pest, *Selandria* or *Blennocampa Cerasi*, is sufficiently marked out as distinct; and one of its peculiarities is that the full-grown grub does not descend to the ground, but forms a gummy cocoon upon a twig of the tree. Within this the pupa reposes through the winter, and it is obvious

Fig. 52.—Imago of *Selandria æthiops*, Newman (magnified).

that no amount of syringing is likely to kill it or stop its development.

The flies emerge during June. Of the female insect the entomologist above mentioned writes in his original way—"Her first thought is matrimony; her second thought, or instinct, is preparing for a family. She is always in mourning; even before matrimony she wears the sable garment of widowhood. Her head, antennæ, body, and legs are almost entirely clothed in black. Her wings, otherwise colourless, bear a blackish shade across the middle." Her partner is of similar appearance, and in both sexes we find the habit of shamming death when alarmed, the fly falling as if insensible, with the limbs closely folded together. The eggs are deposited upon the leaves of the Cherry in a small slit made by the parent by means of her ovipositor, each separately. It is a singular circumstance that, from their having a shell of elastic material, these may be seen to increase in size before hatching. From their minute size and pale colour

Fig. 53.—Larva of *Selandria æthiops*, Newman.

the young larvæ are hardly discernible by the unaided eye, and before long they begin to be coated with the thick slime of blackish brown, which originated their popular name. This has an unpleasant smell, though not always noticeable. These slugworms have, in fact, the numerous feet possessed by most larvæ of sawflies, by the aid of which they glide slowly over the leaves, but these organs and the shape of the body are quite hidden by their protective coating. Perhaps owing to this the insects escape partially from the attacks of birds. In feeding they confine themselves to the upper surface of the leaf, keeping near the centre and avoiding the veins. Cherry trees are not only disfigured but rendered sickly by a visitation of these larvæ, upon which syringing and similar modes of treatment have very little harmful effect. The best plan of operating upon it appears to be that of dusting the leaves well with quicklime directly it is observed, as this adheres to the slugworm and speedily kills it. In America, however, it is usual to apply powdered hellebore mixed with water, which compound is thrown upon the trees from above. I would not myself be inclined to advise this remedy for general adoption; indeed it might be dangerous at the time the fruit is setting, unless washed off very copiously.

More than one species of aphid occurs upon the Cherry. The most abundant and hurtful kind is the too well-known "black fly," or *Aphis Cerasi*, conspicuous by its black hue through the

greater part of the season until autumn develops an egg-laying brood, with brown females and brownish yellow males. From these eggs appear the young aphides of spring, and gardeners are rather apt to neglect looking after these until they are troublesome to check. Mr. Taylor has advised diligent syringing before the bloom of the Cherry opens. The solution he recommends is that compound of soft soap, petroleum, and water, the formula for which has been repeatedly published. This is to be applied in the form of a gentle spray to the trees, and also the walls if needful. Quassia water, tobacco water, and other recognised remedies for "fly" have their advocates. It is sometimes necessary, where the pest has been let alone, to cut off freely those shoots on which it swarms.

Some caterpillars of moths occur upon the Cherry. One that is decidedly injurious is that which produces the small ermine moth, *Yponomeuta padella* (fig. 54). This species is not confined to the Cherry, but is, in most years, abundant on the Hawthorn, and visits also other fruit trees, the Apple, for example. It is doubly a nuisance in its larval state, from its not only devouring the leaves of the tree so voraciously, but overspreading the branches besides with a mass of web which is unsightly, and checks the growth of the buds. Yet few natural objects of its size are

Fig. 54.—Small Ermine Moth, (*Yponomeuta padella*).

more beautiful than is this little moth, whose satiny glossy fore wings of white, shading into a delicate grey, are dotted over with about thirty black spots, the hind wings being dark brown. The caterpillar has a resemblance to the moth in the matter of colour. When adult it is whitish, having numerous black points scattered over the body. There are few indications of these caterpillars during early spring, when they burrow within the young leaves; but in May they show themselves upon the masses of web which they spin in company, and if unmolested will very soon strip an ordinary sized tree of its foliage. Having fed up they then spin each a silken cocoon, under the protection of the general web, and the moths emerge about the end of June. Their eggs are deposited soon after, under a patch of gum, and the caterpillars hatch in the autumn, though they do not begin to feed till the next season. It is difficult to find these upon the branches, but syringing or washing would probably remove some of the caterpillars from their hiding-places while young. As they, when older, drop readily on any alarm, the trees may be well shaken, and the fallen caterpillars removed and burnt, or the webs may be cleared by handpicking. It has been recommended to drench the trees well with a decoction of quassia at the time the earliest caterpillars are noticed, and as almost the whole brood of moths emerges together, syringing when they are first seen will kill many as they leave the chrysalis if any of the webs have escaped.—ENTOMOLOGIST.

HARDY FRUIT GARDEN.

Shelter.—Taken in its full sense of protection from frost and cold cutting winds for the tender blossom of fruit trees, shelter resolves itself into two distinct parts—the first permanent, in the form of walls, hedges, and tree belts; and the second, temporary and portable, consists of mats, netting, tiffany, and similar light materials. The best form of temporary shelter is that which can be used at night and removed by day. This plan, however, involves much labour, and generally preference is given to any contrivance that can be left over the trees till the fruit is safe. For wall trees this may be managed by broad coping-boards, from the outer edge of which Nottingham netting is stretched downwards over poles thrust into the ground and fastened to the coping so as to avoid all risk of the blossom being battered by the netting during the prevalence of high winds. In bleak exposed positions the netting may be doubled without keeping the light from the blossom in a hurtful degree. A double covering of this light hexagonal-meshed netting has repeatedly answered so well as a means of protection that we strongly recommend its use also for espaliers, pyramids, and bushes, over which it is stretched upon a light yet strong framework of wood. A little dried fern litter scattered over the tops of Gooseberry bushes now serves to protect the young foliage and blossom from injury by

frost. We have been obliged to put netting over the hushes to keep off hullfinches, and the fern is kept off the bushes by it.

Now is the best time to see if the permanent shelter is as efficient as it ought to be. Walls are too expensive to be extended indefinitely, but hedges of Thuja Lobbi are not, and they make such admirable wind screens—growing quickly even in a poor soil—that there should be several intersecting each other in all large fruit gardens. For enclosing a small fruit plantation they answer better than any other tree. There is still time to plant them if due care is taken both in the transplantation and in carefully mulching them with litter, or better still with rough half-decayed manure. Let the provisions of means of shelter extend beyond the garden, and make good any want of tree shelter, by planting thick groves or belts of Spruce, Silver, and Larch Fir upon the north and east sides. Let, also, the baneful effects of cold cutting north-eastern winds and of late frost in valleys at this season of the year not be forgotten if you are selecting the site of a new fruit garden, and if possible choose a sheltered sunny south-western slope for the purpose.

FRUIT-FORCING.

VINES.—Early Houses.—If the remains of the fermenting materials ought to be removed from the inside borders before the Grapes begin colouring, leaving only sufficient for a mulch, and giving a thorough soaking with tepid liquid manure. The mulching will keep the roots active near the surface and prevent evaporation. Maintain a good moisture in the atmosphere by damping well at closing time. Allow a fair amount of lateral extension, which will materially assist the Vines in swelling off their crops, but do not allow growth to be made which must afterwards be removed in quantity.

Succession Houses.—Continue disbudding, tying, and stopping, allowing two joints beyond the show of fruit, and the laterals may be allowed to make as much growth as there is space at command without crowding the principal foliage, which, under any conditions, must have full exposure to light and air. Thinning the bunches must be attended to in good time, commencing with the freest setting varieties as soon as they are out of flower, having previously removed all surplus and ill-shaped or imperfectly fertilised bunches. This needs some judgment and not a little firmness, as a great crop is sometimes sought for the sake of appearance, which can only be had at the expense of the Vines, and mostly results in bad finish. Where Grapes are setting keep up a circulation of dry warm air, but avoid currents or draughts, especially of cold air. Should the bunches exhibit by curling a disposition to run into tendrils, which is not infrequent when the wood has not been properly ripened, the moisture should be reduced and the temperature kept a little higher. When Hamburgs are in flower a minimum temperature of 65° at night and 70° by day should be accorded, and for Muscats it ought to be 5° higher. Gently shake the Vines occasionally to liberate the pollen, and pass a camel-hair brush over shy-setting varieties, using pollen from Black Hamburgs.

Late Vines.—When these have started into growth gentle fire heat will be necessary to keep them in steady progress. Vigorous young canes do not break freely, hence they should be brought down to a horizontal position to prevent a rush of sap to the terminal bud, and when all the eyes have started they may be tied up to the wires. Syringe twice a day, but sufficiently early to allow the Vines to become dry before night. Admit a little air at 70°, and encourage a free growth by closing with a humid atmosphere at 75°. Late houses of Hamburgs should be allowed to start naturally, keeping the houses freely ventilated above 50° for the present.

Vines in Pots.—Give liberal supplies of liquid manure to those swelling-off their crops of fruit, and renew the top-dressing where necessary. When the Grapes commence showing colour allow a circulation of warm rather dry air constantly, but do not lessen the moisture all at once, but gradually, as the Grapes swell considerably in finishing, and must not lack moisture at the roots nor have a dry parching atmosphere. Pot young Vines from this year's eyes as they break into free growth, plunge in gentle bottom heat, keeping them close and moist for a few days, and when they have taken to the new soil fully expose to sun and light.

Melons.—The earliest plants in a heated house are now swelling-off their fruits, and have been earthed-up. Do not allow the growth to extend much, but stop, tie, and thin out the shoots so as to prevent overcrowding. Remove all blossoms from plants swelling-off their fruit, and finally earth-up if it were only partially done when the fruits commenced swelling. See that the plants do not suffer from insufficient supplies of water, and when the roots are working freely in the fresh material afford copious supplies of tepid liquid manure, being careful to keep it from the stems of the plants so as to avoid canker. Maintain a bottom heat of 85° to 90°, and keep the day temperature at 75°, and between 80° and 90° from sun heat, closing at 85°. Ventilate early avoid cold currents, and syringe twice a day, damping well before nightfall, but be careful to have the foliage dry. In succession houses attend to stopping, tying, and regulating the growth, avoiding overcrowding, impregnating the blossoms on fine days, and stop one joint beyond the fruit.

PLANT HOUSES.

Chrysanthemums.—Those who grow these plants for decoration should strike a good batch without further delay. Select for the cuttings good vigorous shoots, which may be inserted singly in small pots and placed in a temperature of 50° to 55°, where they will soon form roots. They can either be placed under handlights or not as long as the cuttings are

shaded from strong sun. As soon as roots are formed the plants should be plunged into a hotbed prepared in a frame, where they will receive gentle heat for a time. By this system the plants are not checked in being removed from warm to cool quarters, for they are gradually prepared for cold frame treatment as the heat of the bed declines. Gentle heat afforded the plants by this means is very beneficial; if air is carefully admitted they will grow strongly. Before they are plunged in the hotbed the young plants should be transferred into 4-inch pots; employ as compost good loam, a little leaf mould, and coarse sand.

Roses.—Perhaps at no season of the year are *Roses* indoors more subject to mildew than about the present time. The sun is getting more powerful, and air often has to be admitted when the wind is cold. Every precaution must be taken to prevent cold draughts, for nothing will cause this destructive parasite to establish itself sooner upon the foliage. The plants should be diligently syringed with the softsoap mixture recommended from time to time, and if mildew appear add a little flowers of sulphur to the softsoap water, and if one application does not prove effectual syringe for two or three days in succession with the same mixture.

Those who force these plants early will now have wood in good condition for cuttings, which root quicker when scarcely half ripened. Two joints are ample for the cuttings, and both leaves should be left upon them, the top eye only being left above the soil in which they are inserted. The cuttings must be inserted as quickly as possible after they are severed from the plants. They can either be covered with bellglasses or placed in a box covered with glass, which will do equally well if rendered air-tight. If a good watering is then given no more will be needed until they are rooted, which will be in about three weeks. The boxes or pans containing the cuttings should be placed in a temperature of 60° and kept shaded from strong sun. Air should be gradually admitted after they are first rooted, and then the young plants may be transferred into 3-inch pots. They should be grown in heat for a time after they are rooted until they are established in their first pots, and then be placed in an intermediate temperature. It is surprising what fine plants can be produced by autumn from cuttings inserted now, and quantities of buds will be produced from such kinds as *Safrano*, *Niphetos*, *Madame Falcot* and others. The Hybrid Teas are also very good for this purpose, especially *La France* and the *Hon. George Bancroft*. *Gloire de Dijon*, *Maréchal Niel*, and others of similar growth will, if well grown in 10-inch pots, give abundance of fine flowers early next year. No *Roses* give better returns than the last two mentioned when grown on annually for forcing early.

Deutzias.—Few flowering plants are more useful for forcing than this hardy shrub, and the young tender shoots will root freely and quickly at this season of the year. The points of growing shoots about 2 inches in length are the best for cuttings, which should be inserted thickly together in pots or pans covered with bellglasses, or placed in a close frame and kept shaded from strong sun, and in about a fortnight they will be well rooted. After they are rooted, and before their roots become matted together, plant them out in boxes or large pans about 2 inches apart. Grow the plants in gentle heat and pinch the young plants to keep them bushy. They can afterwards be planted outside about the end of June, or placed in small pots and grown on, the former being preferable, as, when planted out, they need less labour. Plants rooted now will in two seasons be fine specimens in 5 and 6-inch pots for forcing.

Prunus sinensis.—The double form is one of the best plants we possess for forcing, very little heat being needed to bring them into bloom, and a good succession can be maintained by introducing them into heat at intervals of a few weeks. Those that have flowered will have good cuttings upon them, which root freely if slipped off with a small heel when about 2 or 3 inches in length. The cuttings may either be placed together in pans or pots and covered with bellglasses, or about three may be inserted in small pots in a close frame and then grown on together without disturbing them. This plant requires the same treatment as *Peaches*, and will grow luxuriantly in heat and moisture, but requires to be well ripened to bloom them well. Cuttings rooted now in small pots and grown on without being disturbed at their roots, will in one season make good flowering plants; but in two years they will make fine specimens large enough for all decorative purposes. This shrub thrives better in pots than planted out.

THE FLOWER GARDEN AND PLEASURE GROUND.

Methods of Propagating Bedding Plants.—There are various methods of striking cuttings of such bedding plants as *Verbenas*, *Heliotropes*, *Ageratums*, *Iresines*, *Marguerites*, *Coleuses*, *Alternantheras*, *Fuchsias*, and *Konigas*, these being adopted according to circumstances. Where large numbers are required, the room for propagating being proportionate, boxes about 24 inches long, 15 inches wide, and 6 inches deep are the most suitable for the purpose. These should be well drained, about half filled with a fine compost, and surfaced with silver sand. The tops of young growing shoots to be trimmed and dibbled in so as to just clear each other, watered in, and covered though not touched with two squares of glass. They may be stood on either the beds, stages, or floors of the forcing houses, but not where they will be too quickly dried by the hot-water pipes. If strips of paper are pasted over the edges of the glass so as to exclude all air from the cuttings, they will strike still more quickly and surely. Where the conveniences for propagating are limited much may be quickly done with saucers filled with sand and water, these, when filled with cuttings, being stood on the troughs of the hot-water pipes. Very few cuttings will fail to strike quickly in this manner, but care must be taken to use light well-warmed soil when boxing and potting

them, or some will not grow. Frames on hotbeds are largely employed for propagating purposes, and here the steam arising from badly prepared heating materials is most destructive. Well-drained pots and pans are better than boxes in this case, and good light sandy soil should be used. Avoid crowding the cuttings, and do not cover with glass, otherwise they are more liable to damp. Small frames may in some cases be easily extemporised over the boilers, or at the warmest corner where an angle is formed with the pipes, the latter to be surrounded with brick rubbish, and over this placed a good depth of cocoa-nut fibre and decayed tanners' bark or sawdust. This material should always be kept moist, and the cuttings may either be dibbled into this or it may serve as plunging material for pot and pans filled with cuttings. No air to be given unless for a short time in the morning to check damping. In every case the cuttings should be put in quickly in order to prevent their flagging badly, and should always be carefully shaded from sunshine.

Verbenas.—If there is a good stock of these, propagating may well be delayed, as they strike quickly and are better for being kept growing without a check. They should be grown without much fire heat, otherwise they quickly become infested with aphides, thrips, and red spider. *Verbenas*, including the useful *V. venosa*, can easily be raised from seed sown in pans and placed on a hotbed, and of the former many good sorts may be obtained from one packet, but, being strong growers, are best planted in a group. If any of the long fleshy roots of *V. venosa* have been preserved these should be cut into lengths with two joints and dibbled thickly in boxes or pans of good soil. Placed in a mild hotbed or in a forcing house, they are soon fit for planting out in a frame or in boxes, where they will grow to a good size by the time they are wanted.

Lobelias.—The ordinary bedding *Lobelias* are best propagated by division and cuttings in preference to seedlings, the latter rarely being sufficiently neat-growing. *Bluebeard*, *pumila magnifica*, and *Brighton* are all excellent blue sorts, and supposing a number of plants of either of these have been wintered in boxes in a rather low temperature, on being introduced into an early vinery or in a moist heat every shoot will quickly emit roots. These may be pulled off and dibbled in rather thickly in boxes and eventually bedded-out in cold frames, or, if a little bottom heat is available, these divisions may be placed on beds of good soil and about 4 inches apart each way, where they will soon grow to a good size, the frame or lights being then available for other purposes, some other protection being provided for the *Lobelias*. Thousands of good plants may thus be raised without much trouble. Seedling *Lobelias* should be pricked out before becoming crowded and weakened. The herbaceous sorts may be divided when the suckers are well above the soil.

Succulents.—Excessive moisture proves fatal to these, especially when the cuttings are first inserted. If it is intended to strike the tops of *Echeverias*, *Sempervivums*, *Pachyphitons*, or *Kleinias*, after the lower leaves are trimmed off they should be laid on warm shelves till the cuts are healed, when they may be dibbled into well-drained pots or pans of sandy soil and stood in the full sunshine and in heat, only sufficient water being given to prevent shrivelling. Preserve the old stems, as these will furnish a number of side shoots. *Kleinias* may also be increased by division, and the *Agaves* are similarly propagated. None of them require a very strong heat to grow in, and the popular *Sempervivum tabulaforme* grows the most freely in cold frames. The tops of *Mesembryanthemum cordifolium variegatum* may be dibbled in thickly in pans of sandy soil and stood on warm sunny shelves and kept rather dry. Moisture and shade does not suit them, and the stock plants should be grown in the full sunshine, and then the cuttings will be harder and less liable to damp off.

Annuals for Early Blooming.—Sweet Peas and *Mignonette* are always acceptable, and an early supply may be obtained by sowing a few seeds in pots and planting out when properly hardened off. The handsome new varieties of the former should all be sown in this way, the few seeds contained in a packet being too valuable to be risked in the open ground where mice and slugs are waiting for them. Make the soil firm for the *Mignonette*, and if 3-inch pots are used do not leave more than three plants in a pot. Candytuft similarly treated will also afford a quantity of early bloom. All three may also be now sown in the open, and if a row of Sweet Peas be sown with the culinary sorts and carefully staked a remarkable quantity of bloom will eventually result.

THE BEE-KEEPER.

SEASONABLE NOTES ON BEES.

THE time has now arrived for us to make good our promise to give an account of what we are doing with our bees. Before doing so we would call attention to one or two errors in the punctuation of our last article, which caused it to read otherwise than we intended. At the bottom of page 176 it should read thus, "Does not care for their stings, in season and out of season exposes them," &c. Again on the top of page 177 it should be thus—"Open to inspection from end to end and at any moment, the temptation," &c.

We had in the week ending March 8th two or three most beautiful spring-like days, with warm sunshine and little wind. These are the days to choose for overhauling hives, and we have taken advantage of them to ascertain the strength and condition of each and every colony. We particularly wish to write these instructions for those

who are beginning bee-keeping, and must therefore ask pardon of those readers to whom the advice will be only a repetition of former teaching. It may be supposed that a colony of bees had been carefully wintered in a bar-frame hive; that the owner has followed the plan of proceeding explained from time to time in the Journal, keeping his bees as quiet as possible up to the present time, only seeing that there has been a sufficient supply of food within easy reach of the cluster. He has paid particular attention to the comfort of the bees by wrapping them up warm, and by narrowing the entrance to the hive in order to exclude as much cold air as possible.

It is now wished to set to work earnestly to build up this colony into a powerful army of honey-gatherers. Let him see that his smoker is in a clean and serviceable condition, and that he has a good supply of properly dried fuel for the same. We use nothing but decayed wood, well baked in an oven and then stored for use. Brown paper tied in rolls of convenient sizes is also a good fuel for the purpose. Besides the smoker a long knife, such as a thin carving knife, is useful to have by one's side for the first inspection of a hive after winter. Bees will sometimes throw buttresses from comb to comb, or attach the frames to the sides of the hive, and we wish to sever these attachments with as little jarring of the combs as possible. Some syrup should be in readiness, made of 1 lb. of sugar to half a pint of water, a sprinkle of salt and a dessert-spoonful of salicylic acid solution. A feeder which can be regulated to a very small allowance in the twenty-four hours will be required. Light the smoker and proceed to business.

Double back the quilts one by one from the front part of the hive, standing behind the hive. A few puffs of smoke, delivered on and between the combs exposed to view, will send most of the bees to the centre combs. We then push back the dummy towards the front wall of the hive and gently lift out the first frame. In a similar manner we inspect the the next frame. If both are very heavy with honey and no brood in them we take away one altogether. We will suppose that the bees are wintered on six frames; we now draw back the quilts still more and expose to view the third comb. Here we shall doubtless find brood, and perhaps the queen will also be seen on this comb. Should there be no brood we must search diligently for a sight of her majesty. Few hives with a queen will now be destitute of brood, and therefore if no brood appear the presence of the queen must be ascertained, and if she be there we must note the effects of the stimulative feeding. Should no eggs be deposited shortly we must consider that she is old and worn out, and shall have to decide upon what is to be done with the stock. But we will suppose that when gently lifting the comb from its position there is a densely crowded mass of bees on it, and in causing some to move aside we see the sealed patches of brood, noting the size of the patch, and quickly restore the comb to its position, drawing back the other comb or combs towards it, and then replacing the divider. A puff or two of smoke drives the bees from off the bars, and we then replace the quilts one by one as they were before. We now commence from the back of the hive; having folded back the quilts we draw the divider to the back wall of the hive, and as before carefully but quickly examine comb by comb until we arrive at the one last examined at first.

By commencing at the front of the hive and re-arranging that before opening behind, we keep the bulk of the bees constantly in the middle, and allow less heat to escape from the brood nest than if the whole of the frames were uncovered at one time during the inspection. When handling the entire combs, if there is much honey around the brood we use our knife for uncapping carefully a small quantity of it near to the sealed larvæ. This action has a double purpose—the bees are stimulated to action by the removal of the honey, which they at once undertake, and at the same time the area of brood nest is enlarged, as the queen will utilise at once the emptied cell for the deposition of eggs. The constant and regular uncapping of honey cells is a potent means of stimulating the breeding powers of a colony, but it must be borne in mind that every care is to be taken not to expose the brood even for a minute or two to a cold wind. It is at this season of the year so easily chilled. Having therefore noted the size of the brood nest, the number of frames covered by the bees, and the amount of food in the hive, it is well to make memoranda of the same in order to refer to them at our next inspection. We find nothing better for the purpose than a small slate or tablet tacked to the inside of the cover where hives are outdoors or placed over each hive in a bee house.

We now leave our hive with every facility for increasing in strength, since there are plenty of vacant cells at the queen's disposal close to the already hatching brood. We must now employ the means at our disposal for quickening the laying propensities of the queen. We shall commence by seeing that there are very thick warm quilts over the frames, and that there is no escape of heat from the body of the hive. Instead of thinking of diminishing the thickness of the wrappers it must now be increased, and since there is nothing to fear from the moisture engendered in the hive (for a hotbed kind

of heat is what the brood requires) we are in favour of crown boards, or some substitute for the same, during the early breeding season. Flat boards are placed over the quilts to prevent evaporation, and feed over these boards.

There are various kinds of feeders (their name is legion), and we leave the bee-keeper to adopt one to his own liking. A steady gentle supply of food is what is requisite, and so given that there is no inducement to robbery offered to the bees from other hives. Care must be taken to spill no syrup about the apiary, and to keep all vessels containing syrup well covered. Mice as well as bees like syrup. The top was knocked off a wide-mouthed bottle containing some syrup, and we found three mice in the same. Bottled mice preserved in syrup is at any rate a novelty. If bees once learn where the syrup is kept, or where it is fed to other hives, it is astonishing with what pertinacity they return again and again to the spot, long after it has been withdrawn.

After the syrup has been given to the stock for a week, say at the rate of half a pint in twenty-four hours, again examine the hive, this time spreading the brood, and gradually continue to do so on each examination afterwards. At first only remove the inside combs of the brood next to the outside of the same—that is, simply reversing their position. This will be followed later on by a greater extension, caused by inserting a sheet of foundation between the combs already nearly covered with brood, and so proceed until at length the greater portion of the body of the hive is converted into a brood chamber. But we hope to speak of this more fully in another letter.—P. H. P.

DEATH OF MR. PETTIGREW.

WE regret to announce the death of our old and valued correspondent Mr. Alexander Pettigrew, which occurred at Bowdon, Cheshire, on the 10th inst. As a portrait of this earnest apiarian and excellent man appears in our issue of September 8th, 1881, with his autobiography, it is not necessary to repeat here the details of his life. As a gardener he was able, as an apiarian successful, as a member of the community one of the most worthy. He was from youth to old age an earnest seeker after knowledge, and what he acquired he took great delight in imparting to others. He commenced writing for the press forty years ago, and continued without intermission until within two years of his death. His communications to our columns were voluminous and appreciated, and his popular "Handy Book on Bees" has passed through several editions. He clung with characteristic tenacity to the value of large straw skeps for bees, simply because he found they gave him the greatest bulk of honey in return for the least outlay in labour, and also because he could always find a market for his goods, but latterly especially he admitted the great value of the bar-frame hive and the sectional system of management.

Perhaps no one has done more to advance bee-keeping than Mr. Pettigrew has during the period indicated. He was a persevering teacher long before the art became fashionable, and numbers of persons in this and other countries have benefited by his experience, which he so readily communicated through the press. He was a forcible and occasionally a pungent writer, and if he ever found that he had unwittingly given even the slightest pain to a controversialist his letters always showed that he inflicted even greater pain on himself.

Honest and upright in all his dealings, intellectual in character, an agreeable companion, a fast friend and a model parent and husband, the memory of Mr. Pettigrew will be cherished as of one who endeavoured to do his duty and to leave a good name behind him. He leaves a widow, with whom we sympathise in the great loss she has been called to endure.

TRADE CATALOGUES RECEIVED.

James Dickson & Sons, 103, Eastgate Street, Chester.—*Catalogue of Farm Seeds.*

H. Cannell & Sons, Swanley.—*Catalogue of Chrysanthemums.*

Charles Turner, Slough.—*General Spring Catalogue for 1884.*

W. P. Laird & Sinclair, Dundee.—*Price Current of Agricultural Seeds.*

Dickson & Robinson, 12, Old Millgate, Manchester.—*Select Farm Seeds.*

* * All correspondence should be directed either to "THE EDITOR" or to "THE PUBLISHER." Letters addressed to Dr. Hogg or members of the staff often remain unopened unavoidably. We request that no one will write privately to any of our correspondents, as doing so subjects them to unjustifiable trouble and expense.

Correspondents should not mix up on the same sheet questions relating to Gardening and those on Bee subjects, and should never send more than two or three questions at once. All articles intended for insertion should be written on one side of the paper only. We cannot reply to questions through the post, and we do not undertake to return rejected communications.

Books (R. C.).—A full chapter on Auriculas is included in our "Manual of Florists' Flowers," price 4d., post free 4½d. A larger work dealing with these plants is Mr. J. Douglas's "Hardy Florists' Flowers," which can be obtained from the author, The Gardens, Great Gearies, Ilford, Essex.

Worms on Lawns (G. H.).—We know of no safer or simpler plan for cleansing lawns of worms than saturating the ground with clear lime water. A peck of lime placed in a cask with forty gallons of water will provide what you want. It will need to be skimmed, however, and used in a perfectly clear state. It will not injure the grass, but will bring the worms to the surface, from which they can be swept and disposed of.

Pruning Holly Hedges (Sussex).—There is no better time for trimming Holly hedges than during mild weather in April, as the sap is then becoming active and the after growth is quick. It is well also to go over them in August, shortening any growths that are unduly vigorous, and a more equal growth and better furnished hedge will result. A knife is much better than shears for the work in question, as severing the leaves, which must occur when shears are used, mars the effect of the work.

Converting a Slope into a Terrace (J. T. S.).—Your plan of dwarf walls would answer very well, and might be rendered highly ornamental with balustrades of open stonework and vases or tazzas along the top, continuing the balustrades down the sides of each flight of steps. A much less expensive and equally efficient plan would be to substitute short turf slopes for the walls if there is sufficient space for them. Before taking the whole of the long slope in hand let a section of it be dressed into as many levels and short slopes as may appear necessary, in order that you may study the effect and make any alterations without unnecessary outlay.

Exhibiting Conifers (E. P. C. B.).—We should not send any of which you have a doubt as to the accuracy of the names, nor any that are very small. Let what you forward be sent as typical examples of good growth, and as indicating the natural advantage of your district for the growth of the plants or trees. We should not remove more of the tap roots than is necessary for enabling the transplanting to be done in boxes conveniently and well. They should be well watered at the roots, and sprinkled occasionally over the foliage, and shaded for a time if the weather be bright. They would be established the sooner if placed in a house or frame and kept rather close for a few days or a week. This, however, is not essential, and with careful management you may succeed without any such aid.

Old Ashleaf Potato (Loughgall).—In reply to your question, Mr. Iggulden writes:—"If 'Loughgall' will refer to page 183 he will observe I did not state this good old sort 'can still be had.' It is still cultivated in several private gardens, but I am sorry to say I cannot inform him where he can purchase any seed. It is a pity someone does not work up a large stock of it, as there is no doubt about its being the best early Potato in cultivation. The tubers are not unlike Veitch's Improved Ashleaf, but the sprouts are much thicker and are of a reddish green colour, whereas those in Veitch's and other early Ashleafs are generally purple. The greatest quantity of it I have seen was grown by Mr. Taylor at Longleat, and I believe Mr. Bardney grows it extensively, and may be able to state where it can be bought."

Cucumbers and Tomatoes (A Lancashire Reader).—We have never seen finer crops of Cucumbers and Tomatoes than in an instance where both were grown in the same house; it was, however, a span-roofed structure, having Cucumbers on one side and Tomatoes on the other, still it afforded conclusive evidence that the temperature and management were equally suitable for both crops. We perceive you wish to grow Tomatoes on the back wall and Cucumbers on the roof. If you plant very strong Tomatoes, and have them as much as possible in advance of the Cucumbers, you may succeed in having a fair but scarcely a heavy crop of the former. We have seen very useful Tomatoes grown on plants trained to the back walls of vineries, but the houses were lofty and probably lighter than yours. You have little to lose in trying the Tomatoes as suggested, as they are more likely to succeed than Cucumbers in the position in question, and with care in setting the fruit and good management generally you may possibly obtain some good dishes of fruit.

Seedling Cineraria (J. H.).—Although you endeavoured to pack the flower so that it should reach us in a fresh state, you quite failed in your object, as most persons fail who use cotton wool instead of moss for packing. The florets are very broad and the colour rich, but we cannot judge satisfactorily of the form of the flower owing to the curled and partially shrivelled florets. We are, however, pretty certain the variety does not possess nearly equal merit with the best that are certificated by the Floral Committee of the Royal Horticultural Society. You will be quite justified in naming the variety and growing it under name, but we do not apprehend it has any particular commercial value, as we scarcely think a florist who grows the leading varieties for sale would purchase it.

Root Culture of Vines (J. A.).—The remarks of Mr. D. Thomson to which you refer apply equally to inside and outside Vine borders. Unless the soil is filled with active roots, and especially near the surface, it is very easy to waste much money in the purchase of prepared manures for dressing the borders. We have known many pounds' worth of fertilisers applied to Vine borders which contained few or no fibrous roots, while where these were working nothing was applied to the soil. The majority of the fibrous roots of Vines are often in a very different part of the garden from where the owner expects them, and he consequently wastes manure by applying it in the wrong place. We have seen many instances of this. We also know of still more, where manure is wasted because given in excess on account of there being so few active fibrous roots in the soil to absorb its virtues. The practice described by Mr. Thomson of encouraging the increased production of surface roots is exactly in accordance with advice that we have en-

deavoured to give on various occasions. A network of active roots close to and bristling through the border may be regarded as the first essential towards success in Vine culture, and of infinitely greater importance than any amount of artificial manures of whatever kind applied to borders which contain few of such roots. Mr. Thomson takes care to provide roots before he gives top-dressings, and this is what everyone should do who desires heavy crops of fine Grapes. Even inside borders may with advantage be mulched with manure, and the moisture and food will attract the roots upwards; whereas if the surface of the soil is allowed to be loose and dry they are inevitably driven downwards either into inferior soil or out of the border altogether, and brick walls will not stop them unless the bricks are laid in cement.

Carnations not Flowering (J. S.).—A temperature of 65° by day and 55° by night during the dark days of winter is too high for Carnations, but we do not think that that was the sole cause of the failure, and in all probability the plants had very different treatment in the nursery in which they were grown than they received after you obtained them. For instance, they may have been grown in a pit, the pots plunged in cocoa-nut fibre refuse or some other moist medium, and exposed fully to the air by the removal of the lights in all favourable weather. If this were so, which is probable, the check they would receive by being placed on the dry stages of a house and kept too close and warm would be quite sufficient to cause their collapse. The secret of growing good plants for winter flowering is to raise them annually from strong and sturdy cuttings, and to keep the plants strong, sturdy, and freely growing throughout the summer, either in the open air after May, or in pits from which the lights can be drawn if the locality is very cold and heavy rains prevalent. The full details of culture cannot be given in this column. We shall shortly publish an article by a successful grower of these plants that will be of more service to you than anything you can find in any book with which we are acquainted.

Treatment of Orchids—Heating (L. I. K.).—The Cattleyas will require a continuation of good treatment to insure strong growth this season, which must be well matured. Supply them liberally with water, and maintain a good temperature in the house. Dendrobium Cambridgeanum will also require rather more water now, but the D. Jamesianum must be in bad condition. Turn it out of the pot or basket, remove all the old material and employ fresh healthy sphagnum and fibrous peat, placing the plant in a warm position for a time, and supplying water very carefully until fresh growth is being made. An excellent article on potting Orchids will shortly be published that will be useful to you. The number of feet of piping your boiler will heat depends upon the superficial area exposed to the action of the fire. Every square foot of such surface is estimated to heat 40 to 50 feet of 4-inch pipes, or 55 to 66 feet of 3-inch pipes, but this is only approximate. If the pipes and boiler are connected by 3-inch pipes the circulation will be quicker than if the smaller size is employed, otherwise it is of little consequence.

Sulphate of Ammonia (F. H.).—This active fertiliser is best applied in the form of a top-dressing to crops in a growing state in spring, and that are not making satisfactory progress. Sprinkled over the roots, not the foliage, in showery weather, at the rate of from 1 to 2 ozs. per square yard, hoeing the ground as soon afterwards as possible, usually has a marked effect in expediting growth. It accelerates the movement of all green crops, promoting the increase of stems and foliage; but if given too freely, or to crops that are already growing freely enough, it is calculated to do more harm than good. We have known Potatoes, Peas, and Beans rendered over-luxuriant by its use, and not bearing freely in consequence. In such cases there is not only a loss of the fertiliser that is applied, but the strong-growing plants deprive the soil of other constituents, and do not give a corresponding return. It is in the same way that some farmers have made the land poor by using nitrate of soda and sulphate of ammonia too freely to their corn crops. But while we have known loss incurred by the injudicious use of the fertiliser in question, we have seen great benefit result when it has been applied wisely. It is almost impossible to teach a person when and in what quantity to apply powerful stimulants, and to what crops to apply them, without knowing their condition and the nature of the soil. By far the best plan is for each individual to use the fertiliser experimentally on the lines indicated, and note its effects on his soil and crops. For plants in pots a pinch between the finger and thumb is sufficient for sprinkling on the soil of a pot 5 inches in diameter, or, if mixed in water, a quarter of an ounce of the sulphate to a gallon of water will suffice; but in neither form will it be of benefit until the plants need more support than the soil affords.

Vines for Late Grapes (H., Belgium).—We presume you require the Grapes for commercial purposes, but you do not say so, and you appear to want a number of varieties. For the house you describe, which, properly managed as regards heating and ventilation, would answer very well, you will probably find Muscat of Alexandria the best of all white Grapes, and Gros Colman the most profitable of the black varieties. Mrs. Pince's Muscat is better in flavour, but does not usually bear so heavily nor colour so well. Lady Downe's Seedling keeps later, but is much smaller in bunch and berry, yet good well-kept crops are profitable. Black Alicante is one of the most certain bearers, and the massive bunches of well-coloured berries have an imposing appearance, but the quality is not of the highest, neither, indeed, is that of Gros Colman, as a rule, though it is often very good, but the size of the berries of these last two varieties when well finished usually tempts purchasers. All the varieties named may be grown in the same house, but we should not include the Duke of Buccleuch except it was particularly desired, and we should then only plant one Vine as a trial. The Muscat of Alexandria succeeds quite well on its own roots, and so do the others; in fact, you can only purchase young Vines on their own roots in England. You can graft or inarch afterwards if you prefer. The Muscat of Alexandria makes a good stock for most varieties of Grapes, and Gros Colman succeeds well on the Black Hamburgh. We never recommend dealers; it would be most unfair for us to do so. Good Vines have been many times advertised in our columns, and possibly they may be found in the present issue. It is quite time that Vines are purchased for planting this spring, as if the buds swell materially they are liable to be broken off in transit. We are not sure that we understand the height and width of your house—namely, 22½ feet. This is an extraordinary height. Without a sketch drawn to scale of the house

we cannot enter into the details of heating, nor must you expect us to recommend any particular boiler or manufacturer. Cannot you gain practical experience on this matter by visiting one of the large horticultural establishments, of which there are so many within easy reach, where methods of heating can be inspected?

Names of Plants (Reader).—*Charieis heterophylla* (*Kaulfussia ameloides*). (*Eighteen-years Subscriber*).—1, A species of *Aristolochia*; 2, A Palm (*Attalea* species); 3, *Lagenaria vulgaris*; 4, *Acacia lophantha*. (*R. B.*).—1, *Narcissus pallidus*; 2, *Narcissus minor*; 3, *Scilla bifolia*; 4, *Scilla bifolia rosea*. (*G. W. B.*).—*Dendrobium Findleyanum*. (*W. E. B.*).—1, *Ranunculus Ficaria*; 2, *Mercurialis annua*; 3, *Scilla sibirica*; 4, *Cochlearia officinalis*. (*D.*).—1, *Anemone coronaria* var.; 2, *Cœlogyne flaccida*; 3, *Calanthe maculata*. (*W. S.*).—The *Cineraria* is an ordinary variety of no particular merit. The other specimen was very imperfect, but appears to be *Scilla bifolia alba*. (*Bridge of Allan*).—1, *Maxillaria picta*; 2, *Selaginella caulescens*; 3, *Adiantum assimile*; 4, *Adiantum Williamsii*; 5, *Pteris cretica*; 6, *Asplenium fœniculaceum*. (*A Constant Reader*).—Both the leaves sent are those of species of *Anthurium*, but are insufficient to enable us to determine them. Certainly they produce flowers. The Orchid is *Dendrobium Jamesianum*.

GRASS SEEDS FOR ALTERNATE HUSBANDRY.

THIS is a subject of great importance in the cultivation of arable farms, and requires a more lengthened notice than appears at first sight, for we have not only the latest improvements to consider, but also as to how they can best be applied to the various soils and climates of this kingdom. At the same time we must endeavour to adapt the seeds to the different systems or rotations of cropping, especially noticing the number of years which the land may be required to lie in grass, and the stock which may be kept for the consumption of the produce whether in hay, ensilage, or field grazing. Hitherto this subject has been most unfortunately neglected by many farmers who have continued certain plans and practices which were customs, and frequently the prejudices, of former times. But we have also some changes to provide for, which even now are not generally accepted by agriculturists, being still regarded only as experimental, and which nothing but actual and careful comparison with former management can decide whether to adopt or abandon.

We have now to refer to those rotations which will go far to influence our selection of seeds, for there are various points to be considered. The ordinary four-course rotation or Norfolk system of cropping consists of, first, fallow, green crop, or roots; second, Lent corn or spring Wheat; third, Clovers, &c., for mowing or feeding; fourth, Wheat, by once ploughing out of grass and Clover lea. It is necessary to consider whether the Wheat eddish should be autumn fallowed, sown with catch crops, or sown in the Wheat for grazing previous harvest and the winter fallow ploughing. We have previously omitted Italian Rye Grass, as though it was of no use, which is true if mixed with permanent Grasses for the production of a good turf as permanent pasture, but in alternate husbandry the case is

altered. On the first introduction of this Grass from Lombardy about the year 1883, a neighbouring amateur farmer purchased some seed at one guinea per bushel, its growth attracted our attention, and we thought it may be judiciously grown, being sown in the Wheat in the spring for autumn grazing, for at that time our flock always consisted of the best and most forward lambing horned Dorset or Somerset ewes. For feeding these ewes and their lambs on the Wheat eddishes we found it invaluable without disturbing our four-course rotation of cropping, and have frequently folded off this Grass for grazing two or three times before breaking up and ploughing for the winter fallow. We have never found this Grass more valuable in use in any other way, for we have often made the choicest sucking lambs and sold at Christmas time, neither ewes nor lambs having received any other food but grazing on the Italian Rye Grass.

The above way of seeding is available if the seed is clean, but unfortunately the seed is often sold in this country containing the seeds of the worst grass or weed which can be found in any mixture—viz, *Agropyrum* or *Triticum repens* (Couch), and on this account much objection has been taken to the use of foreign seed for many years. It is also known that it does not suit the English climate, and that it does not maintain its character for early and successional growth in adverse seasons. It is, however, most important to notice that new varieties through selection and growth in this country are now sold, and are not only valuable for their evergreen and quick successional produce, but from having been raised in this country by judicious selection, they will be more likely to maintain their characteristics through having been grown in our climate. As several seed-growing firms offer their own home-grown seeds of "evergreen" Italian Rye Grass they will prove valuable in a mixture for the purposes of alternate husbandry, but especially in mixtures for one or two years lea.

In the four-course rotation the Clovers follow the Lent corn, and are seeded for in the spring; now it is notorious that the broad or red Clover in the majority of soils will not bear a constant repetition on the same land, for although it may be a fair plant in the autumn, yet it dies away during winter, and the land is then considered Clover-sick. It is, however, not so generally known that when *Trifolium* is grown as a catch crop it frequently insures and secures with greater certainty the red Clover when it follows *Trifolium* in succession. Be this as it may we must provide against the failure of red Clover, and do our best to provide a substitute for the loss of the Clover plant, which has for many years been considered a prelude to the loss or injury of the Wheat crop which succeeds it. In the four-course rotation in consequence of the value of the Clover roots which in their death and decay furnish the most valuable manure for Wheat, and this is one of the points to be considered, in order that in the case of failure of the red Clover we may obtain a sufficiency of deep-rooting Grasses and their stems, which when ploughed-in out of lea shall furnish as valuable manure or nearly so as the red Clover roots are found to do, therefore in ordinary cultivation and seeding the common Rye Grass from time immemorial has been seeded in mixture with red Clover, and in consequence when failure of the Clover occurred no manurial remains were available to plough-in for Wheat. As the question of green and vegetable manuring is now better understood, our mixture must contain seeds which will, after being mown or grazed with cattle, leave a large amount of roots and stems, which when ploughed-in shall manure the land with certainty for the Wheat crop. We therefore recommend the mixture as follows, for seeding in Lent Corn or spring Wheat the latter being best; where the land is not Clover-sick. First course, sow per acre—

	lbs.
Red or Broad Clover	9
Giant White or Dutch	3
Evergreen Italian Rye Grass	4
Cock's-foot Grass	6
Timothy Grass	3
Total per acre	25 lbs.

SECOND OR ALTERNATE COURSE, SOW PER ACRE.

	lbs.
Giant Perennial Cow Grass Clover	9
Alsike or Hybrid Clover	3
Evergreen Italian Rye Grass	4
Cock's-foot Grass	6
Timothy Grass	3
Total per acre	25 lbs.

These alternate seedings are advised, as the red or Broad Clover grown only once in eight years is more likely to retain its plant. The seeding just mentioned will apply chiefly to heavy or medium soils, furnishing crops adapted for mowing or grazing with cattle or sheep. We must, however, next refer to soils whereon sheep only are accustomed to graze, such as chalk, gravel, sand, or limestone, and it should apply to a rotation whereby the Grass lea is expected lie for three or four years, principally for sheep-feeding; but still

we must look to the advantage of having a well-covered lea of stems and roots of Grasses for ploughing-in as a preparation for a cereal crop, such as Oats or drege, or probably Wheat, for the rotation would probably be as follows : Wheat out of lea, fallow for roots fed-off, Lent corn in which the seeds will be sown to remain as follows :—

SEED FOR AN ACRE.						lbs.
Sainfoin, milled seed	14
Giant White or Dutch Clover	5
Yellow Suckling ditto...	4
Crested Dog's-tail Grass	4
Yarrow (Milfoil)	3
True Sheep's Fescue	4
Total seed per acre						34 lbs.

In this mixture we have included those Grass seeds which are peculiarly adapted to dry, stock, or hill farms for furnishing pasturage for sheep of the best quality and the most productive in seasons of drought. At the same time, when the lea is ploughed it will furnish a valuable turf of roots and stems as manure for the succeeding crop in the rotation. We have introduced Sainfoin into this mixture, although it is frequently said it will not answer except on land with chalk or limestone subsoils, but this is not the case exactly in our experience, for we have known it take well on various dry soils where the land was not deficient in chalk or lime, which been applied in its cultivation. So long as we are considering the question of seeding for Grasses and Clovers it will be found that we have cautiously looked forward to possible events or circumstances which may render it beneficial to the farmer to alter the rotation, and thus be prepared for any and every change at all likely to make the growth of the cereals more profitable than at the present time. Under the rotation and seeding recommended, whether the lea is ploughed for cropping with cereals or any other produce, the lea will furnish abundance of roots and stems to manure the land quite irrespective of the droppings of sheep or cattle which may have been feeding on the leas.

We will again call the home farmer's attention to seeding before named for medium or heavy soils, for we contend practically this mode of seeding enables him not only to break up the lea at one year under any rotation with benefit, but place him in a position to throw every field seeded in this way into permanent grass without any further expense of re-seeding if circumstances should require it. It must also be remembered that in those cases where a dairy is kept the produce will be available for hay, ensilage, or feeding by dairy cattle, and young cattle of any description, and thereby adding to the resources of the farm under any circumstances in which the farmer may be placed. Again, there is another point to be considered upon the question of the cultivation of flat-lying heavy clays, such as those termed London clays, which are frequently ploughed in 8-foot ridges. Now, the usual course or rotation of cropping is as follows :—Wheat, Lent corn, and seeds. If, however, the seeding we have recommended is adopted upon such land, if it is clean and free from couch there is no reason why there should be a fallow at all if the lea was ploughed in early and sown with Wheat, when the rotation would be as follows :—Wheat out of lea, Beans or Peas, Oats, or drege, grass seed mixture as above stated for heavy or medium soils.

WORK ON THE HOME FARM.

Horse Labour.—Although the general horse labour is forward in most districts, yet delay has occurred to some kinds of work. It is time now to begin the seeding for Lent corn on all soils, but on some flat-lying strong land the drilling of Peas and Beans must be urged forward. It is now too late to lay out composts of earth and dung upon pastures intended for mowing, but where they are intended to be grazed by cattle and sheep it is not too late if a few dry days should occur. After these composts are laid out and spread they may be soon ready for chain-harrowing and rolling. This will serve to fix the manures to the surface, and with the assistance of the usual showers of April will advance rapidly, and the cattle in feeding on the land will tread in the compost and render it effective for the whole of the summer. These dressings are necessary, more particularly where dairy cows are fed, because they rob the pastures more than any other cattle. Some labour will now be required in harrowing and rolling on the young Wheat, especially where it is intended to be seeded with Grass and Clover seeds, for the seeds will generally take well if the previous preparation or crop has been a fallow, Potatoes, or roots fed off by sheep, for by seeding in this way we have known fine crops of Clover after Wheat, and Grass in the Wheat eddish fit for folding twice in the autumn if Rye Grass, but in Clover we often get an abundant crop fit to mow for the soiling of horses and cattle. We have done this when the autumn season has proved favourable for four or five years in succession. Some farmers will tell us that it injures the growth of Clovers during the following spring and summer, but that is not our experience. When we have mown the Clover in autumn it has always proved superior in growth the next season to any that may have been fed by sheep in the autumn. In case of hindrance on the tillage land set some horses to roll the grass, both in pastures and Clovers on

the arable land; other horses will be for the time when off the land be employed in fetching chalk or lime when near to those districts where chalk soils occur. We are then, after putting the chalk in a dry place, such as a shed or barn, in a position to screen it with the ash screen, so that when the drilling of root-crop seeds begin we may be able to drill screened chalk with the other drill manures instead of ashes as usual. This plan is more necessary and effective upon those soils where the roots are liable to suffer from clubbed roots. Farmers or writers attribute this clubbing of the rootlets to various causes, but the true cause is the absence of carbonate of lime in the land, and which is readily supplied by about twenty bushels of fine chalk per acre. This is a great economy as compared with a heavy dressing of 30 tons per acre of chalk in a rough state, and after it has been applied it is several years before full beneficial action of chalk in the land is obtained. In various parts of the kingdom the chalk pits are but little used or have been for twenty years past, for it is a heavy tax on both landlord and tenant, although they may arrange for each to bear a certain proportion of the expense, although the chalk may be within a few miles of the land to be dressed. It is really the basis of profitable farming, for although we may force much land into a full production of straw, yet the yield of grain will be more or less deficient if carbonate of lime is absent in the soil.

Hand Labour.—This is the month for setting out any draining required on the farm, for after a few hours' rain, when the land dries off on the surface, it is easy to see the extent of the land requiring to be drained, for the dry land will show a white brown colour, whereas the parts which have a wet subsoil will show very dark. Looking at any field from a distance of irregular soil, some of which is too wet, it will be seen as if a chart had been made, coloured to show the wet and dry parts of the field separately. Full employment for women as well as men will now be ready, specially where the planting of Potatoes is going on. Women also on any fields in which the couch or twitch exists only in tufts or bunches, may with great advantage be forked out by women, as it is not heavy labour, and is well suited for them if they are disposed to work. That is not the case everywhere now, although for many years we employed a set of women winter and summer about various kinds of light work to great economy; but this cannot be done without having a number of females at work constantly on the farm, either in the fields or under cover in the sheds and barns as may be required, for where they are constantly employed they are not only better able to do the work of the farm, but their labour is frequently more effective and cheaper in all they are able to undertake than that done by the men, especially if they work only two or three together. The irrigated meadows should now be laid dry and the water turned off from those parts which will be fed by sheep first, and then turned on where the grass will be required for hay or ensilage.

Live Stock.—The working horses of the farm should still receive about 12 lbs. each of roots per day either of Carrots or Mangold, and although during the winter they may have received sweet Oat or Barley straw with their two bushels of Oats per week, yet now this being the commencement of the busy period they should have good field hay instead of straw. The bullocks in the boxes should now be living upon a full allowance of cake not exceeding 4 lbs. and 1 lb. of bean or barleymeal each per day, mixed and given with the cut roots, not to exceed 56 lbs., and we wish it to be known as the result of our experience that they should have only sweet straw without any hay at all, because when well fed in other respects they will enjoy better health at less cost. Lambs fattening for the Easter markets should now receive the best of food in advance of the ewes, but it should be remembered that the ewes likewise ought to receive full allowances of cut roots, with cake and beanmeal strewn over them in the troughs, and the best hay on the farm in addition, for the most experienced shepherds say fat ewes make fat lambs, and this is no doubt true, because they give full quantities of the richest milk.

REMARKS.

9th.—Rain early, then fine throughout.
10th.—Squall about 6 A.M., then fine; rather fine sunset; misty evening.
11th.—Very heavy rain early; fair all day.
12th.—Some fog early, then fine; cooler in evening.
13th.—Fine all day; slight squall of wind at 1 P.M.; cloudy at night.
14th.—Fine morning, and warm sunny day.
15th.—Foggy early, subsequently fine sunny day.
Heavy rains on the first two days, the last two days quite warm and summerlike.—
G. J. SIMONS.

THE APPLICATION OF MANURE IN FRUIT CULTURE.

THAT poor soil requires manure to render it suitable for the cultivation of fruit is certain, but how, when, and in what quantity it is to be used is not by any means so clear, for mistakes have so frequently been made either in using too much or too little, that the exercise of caution in its application has often been advised, often, too, in a manner so vague as to bewilder rather than help. As a safe hint I have repeatedly said that soil which will grow good vegetables will grow good fruit, but even this statement must be qualified. We may plant a Cabbage in crude farmyard manure newly worked into the soil without risk of overfeeding, but to treat a fruit tree so involves the possibility of rampant soft pithy growth, instead of stout, firm, well-ripened shoots. Better would it be, therefore, to say that soil which by good culture has been brought into a suitable condition for the growth of vegetables may fairly be expected to answer equally well for the growth of fruit, meaning thereby soil thoroughly fertile, porous, and well drained.

To reclaim poor land for fruit culture is so costly that if possible it should be avoided, but it has nevertheless occasionally to be done, and as the process will serve to illustrate my meaning more clearly than anything else could do, let us take it by way of example. After the drainage is done we have to see if the soil is deficient of lime and of small stones, if so the deficiency must be made good by the dressing of lime upon the surface, and of sufficient burnt clay or coal ashes to impart mechanical division to the soil so that air may enter and superfluous water pass through it quickly. A dressing of old manure from the farmyard or piggery must also be applied at the rate of thirty to sixty cartloads per acre, according to the actual degree of poverty of the soil, of which the existing growth of trees or grass will afford a tolerably clear idea. The soil is then trenched, the manure, ashes, and lime thoroughly mixed with it, and it is ready for planting. It may be explained that when so mixed in a poor soil lime is of especial value as a decomposing agent among the manure, setting free its fertilising properties, which thus become quickly dispersed among and absorbed by the soil, where it is retained till taken up by the tree roots. If instead of so preparing the whole of the soil stations only are made for the trees, especial care must be taken to use enough shattered stones or coal ashes to prevent the soil of the stations from subsequently settling down too closely. Turf sods are frequently used in stations and afford a rich store of food during the decay of the grass; but eventually the soil in which the sods grew reverts to its primary condition and settles down closely, and then our timely provision of hard gritty matter will keep it sufficiently porous to promote healthy root-action.

If we regard soil as the chief medium for conveying food to plants, we are led to consider what are the plants' requirements and how best to supply them through the soil.

No. 196.—VOL. VIII., THIRD SERIES.

However carefully we may prepare the soil for a fruit tree we know that as its growth progresses it takes from it food which must be replaced, or the tree cannot continue to yield full crops of fine fruit. How are we to replace it? There can be no doubt that the best form in which manure can be applied is in a liquid state. Dissolve, or mix, nitrogen, phosphates, and potash in due proportion with water, pour enough of it over the surface to insure every particle of soil about the roots being moistened, and you have restored its fertility, as it is termed. But I prefer saying we have put a supply of food in it for the tree, because that reminds me that it must be done again in due course. House sewage undoubtedly contains plant food in a most desirable form, and if it were only turned to account in the garden there would be very little complaint of a lack of fertility in the soil. This was one of the earliest lessons taught me in gardening. My father used always to have a man and horse going with the sewage barrel during the season of growth, and the sewage was regularly given to fruit trees of all kinds with most satisfactory results, both in the healthy condition of the trees and in the remarkable crops of fine fruit which they bore.

When we apply farmyard manure to our Vine borders and fruit trees do we know exactly what we are doing? We say that the trees require manure, and we are giving it to them, but they cannot absorb one particle of the mass in its solid condition. It is only when its nutriment is washed down into the soil by rain that the roots, or rather root hairs, can absorb it. So that after all this is but a clumsy method of applying manure, often slow and uncertain in action, and by no means to be compared to the swift sure effects of liquid manure. In a kitchen garden the fruit trees are generally healthy and fruitful, because manure is regularly mixed with the soil near the roots, and there is doubtless a sufficient annual root growth into the fertile soil to maintain the trees in tolerable health, but even there a frequent supplementary application of sewage proves highly beneficial.

Trees that are growing vigorously do not need manurial aid. The soil may, indeed, already be too rich for them; still, if the branches are thinly disposed so that the sun can shine on every leaf, luxuriant young trees will be fruitful in due time. They will yield fine fruit too, not hard, dry, flavourless examples such as are produced by ill-fed trees. It is strong growth in crowded trees—shoots produced in the absence of light and air—that should be avoided. Thin out the branches of strong-growing trees, make the soil firm about their roots, and then—well, let them grow, for even strong growth made under the full influence of the sun and the roots in drained soil will soon be studded with fruit buds, and eventually with fruit. This attained, and the fruit swelling, the benefits arising from copious supplies of liquid manure will be most marked. The grand examples that win prizes at the chief exhibitions are almost without exception the results of a generous system of culture, and never, in fact, come from semi-starved trees.

By turning the whole of the household sewage fully to account in combination with such solid manure as may be available, gardens generally in private establishments do not require the assistance of artificial manure. But in large commercial fruit gardens, and in certain exceptional circumstances some private gardens, its use becomes indispensable, and then a judicious mixture of pure manures should be applied. The manures which I am using on the farm this year are procured separately, and mixed here all of them would doubtless prove useful for the purpose, and I may add the names and latest quotations of prices on rail in London:—Steamed bone flour, £8 per ton; nitrate of potash, £20 per ton; nitrate of soda, £10 10s. per ton; mineral superphosphate, £3 15s. per ton; ground Cambridge coprolites, £3 10s. per ton.

Where only small quantities are required, recourse should be had to some prepared manure from a respectable firm, but

No. 1852.—VOL. LXX., OLD SERIES.

a knowledge of the actual market value of the component parts of such manures is important where a considerable outlay is involved.

The use of pure manures must not be undertaken lightly, however, or much mischief may be done. A correspondent once came to us for advice who had nearly killed his Grape Vines with an overdose of guano; and another who was tempted to apply nitrate of soda to his Celery, used it so liberally that the Celery grew almost as high as his head, and was spoilt.—EDWARD LUCKHURST.

"GARDEN-WORK."

UNDER the above title we have decided to issue a weekly periodical for the million, from the pages of which all who have small gardens in town or country may derive sound information on the culture of flowers, fruit, and vegetables. Our desire is to aid in rendering homes more attractive, and garden plots more profitable. Members of Cottage Garden Societies and allotment holders will find the pages of GARDEN-WORK of great service to them, as will the occupiers of small villa and suburban residences who cherish their gardens, yet who necessarily fail to find the information they need in high-class horticultural publications. All readers of the *Journal of Horticulture* are entitled to a specimen copy of the first number of GARDEN-WORK, which will be posted to those whose addresses are recorded at this office, also to those who procure "our Journal" from local newsvendors on receipt of a Post-card containing the address of the sender. The co-operation of our readers in introducing the new paper to persons in their districts who take an interest in gardening will be cordially appreciated, and any suggestions for distributing copies locally shall have our attentive consideration. As the price of the new paper is only one penny it will be within the reach of all.

NOTES ON ORCHIDS.

DENDROBIUM FINDLEYANUM GIGANTEUM.—The magnificent variety of this Orchid shown by Mr. Salter at Kensington recently is the finest that has yet been obtained, and its merits were duly appreciated by the Committee, who awarded a first-class certificate for it. There is but little difference from the ordinary type, except in size; but in this it is greatly superior, the flower possessing considerably more substance and exceeding 3 inches in diameter, with a fine rounded lip $1\frac{1}{4}$ inch across, and rich golden yellow in the centre. Presumably this has been proved to be a true or established variety, as it is surprising what effects are produced in the size of Orchid flowers by a good system of culture, such as that adopted at Selborne for all the collection.—L.

LÆLIA ANCEPS VAR.—A spirited sale of Orchids was held at Mr. Stevens' rooms, King Street, Covent Garden, on Thursday last, when the chief attraction was a new white variety of *Lælia anceps*, of which some wonderfully large imported masses were offered. The collector describes it as possessing broad sepals and petals, the flowers being over 4 inches across, white, the lip being veined with purple and having two crimson side blotches. The spikes are said to bear as many as six flowers, and Professor Reichenbach considers it to be the variety *vestalis*, of which only one plant is known to exist in England. One magnificent specimen about 9 feet in circumference, with pseudo-bulbs 7 inches long, was sold for seventy-eight guineas after a close competition; others with from fifty to 200 pseudo-bulbs, realised prices ranging from twenty to sixty guineas, according to their health and condition. Very rarely do imported Orchids realise such high prices as these noted, especially when it is remembered that an ordinary *Lælia anceps* can be purchased for 4s. or 5s. At the same sale some fine varieties of *Odontoglossum Alexandræ* were sold at from ten to fourteen guineas each, several being small plants in 60-size or thumb pots. One good yellow-flowered variety was included, and a remarkably beautiful form with rosy-purple flowers—one of the most distinct yet obtained.

ORCHIDS AT OAKHOLME, SHEFFIELD.—There is now a fine display of *Odontoglossums* in full bloom at this establishment, comprising strong plants of *O. Alexandræ*, *O. cirrhosum*, *O. citrosnum*, *O. gloriosum*, *O. nebulosum*, *O. tripudians*, and *O. triumphans*. Of the two first named there are some exceptionally fine varieties, including one of *O. Alexandræ* with round smooth flowers 4 inches in diameter, and of a clear pure white devoid of any spot or marking save a pale yellow patch upon

the lip. The collection of *Odontoglossums* here grown numbers upwards of 150 specimens, which are mostly large, strong, and in the most robust health. A fine collection of *Phalanopsis* is also here grown, and are now flowering well. Amongst them is an extremely fine variety of *P. amabilis* with blooms 5 inches in diameter and very stout, also a very fine specimen of *P. violacea*. *Lycaste lanipes*, which has been greatly admired, has just gone out of bloom. I am surprised this *Lycaste* is not more appreciated by cultivators, as it is both a free grower and a profuse bloomer, and I am of opinion its blooms are more beautiful and striking to the uninitiated observer than the rare and valuable *L. Skinneri alba*. Of two plants flowered here one produced eleven and the other ten of its large creamy-white blooms from a single growth. Mr. Hannah, the gardener at Oakholme, tells me he purchased the bulbs as imported under the name of *Lycaste alba*. He values it very highly.—W. K. W.

CUTTING DOWN DENDROBIUMS.—In answer to your correspondent, "C." (page 223), I here give him particulars of my experience on the subject. About seven years ago, when I took charge of the gardens here, there were two plants of *Dendrobium nobile* in 12-inch pots; these were tied up to stakes about 4 feet long; the plants not having been potted for several years, the aerial roots were as thickly matted together as they possibly could be, and the plants looked very unsightly. The growths not being more than 4 inches long, few of these bloomed. In the month of March I pulled the plants to pieces and made twelve of them; these I placed into 8-inch pots, the compost used being peat, charcoal, and broken crocks. After the plants were potted they were put into a plant stove along with an ordinary collection of stove plants; the house was kept to about 70° at night and from 80° to 100° in the daytime. The plants all grew well, some of the pseudo-bulbs being 2 feet long and 2 inches in circumference by September, in which month they were placed in a vinery, where the Grapes had been cut. There they remained till the following January without fire heat, and only had just enough water to keep them from shrivelling. About the beginning of February some of them were taken back into the stove; these flowered beautifully, some of the growths having as many as two dozen blooms. As I required the flowers to send away, the growths were cut off close to the pot with the blooms on them, when the young growth started from the base of the old pseudo-bulb that had been taken away. The plants were kept in the stove till the following autumn, when they were again removed into a cold house for the winter. This time some of the growths were remarkably fine, being as much as 3 feet 4 inches long, though the plants had not been potted that year and have only been potted once since. This I consider a much better way of growing *Dendrobium nobile* than allowing the old growths to remain on the plants. Sometimes I cut all the growths off a plant as soon as the blooms are open; at other times the plants may have been in bloom a week or two before the blooms are wanted, but I always take the growths out as I require the flowers. My plants look clean and healthy, with no roots up the stems like those usually seen when the old growths are allowed to remain on the plants.—B., *Sussex*

A WORD in favour of an old friend—namely, *Dendrobium nobile*. I was glad to see that your correspondent, "B.," grew such admirable examples of it, and as "C." (page 223) is not sure about the system practised to bring about such good results, I give my experience. As soon as the plants are out of bloom the flower spikes are cut; these are all carefully kept and inserted in pots of sand placed in a corner of the stove and kept moist; the buds that have not been ripened enough to produce flowers very soon start and form small plants, which are taken off and potted when from 4 to 6 inches long. The old stem retains sap enough to keep it producing young shoots for a year from the time it is taken from the plant. I began this system twelve years ago with three plants of moderate growth, and can now count them by hundreds; indeed, I shall be compelled to leave them to their own will very soon for want of room. I think many have failed to flower for want of a proper season of rest. After the growth is made I keep them dry and cool till the flower nodes appear very prominent. This plant is only to be seen in a few places near Glasgow, newer sorts causing it to be neglected, which is a great pity, as nothing is more useful from Christmas until February than a houseful of well-flowered plants.—G. B.

LARGE VERSUS SMALL BRUSSELS SPROUTS.

If any seedsman would introduce a variety of Brussels Sprout which would grow 3 feet high, and have the whole of its stem closely studded with sprouts about the size of a schoolboy's marble and nearly as hard, he might rely on having a better sale for the seed than was ever accorded to the most improved exhibition variety ever introduced. In my opinion we are now running some risk of losing the true type of our favourite

Brussels Sprout, and no greater misfortune could befall cultivators. The Aigburth and all the "exhibition" varieties which have come out of late do certainly produce large sprouts, but this is all that can truly be said in their favour, as they are not packed so closely on the stems of the large as the small ones. The large ones never become really hard. This makes them more easily injured by frost, and when the weather is mild they are more liable to start prematurely into growth, and if any of these are grown slightly in the shade they never form anything like sprouts, but simply a loose mass of leaves. Lastly, apart from all these drawbacks, no ordinary cook or ordinary attention will boil the large ones to be placed firm and entire on the table. The majority of them will fall to pieces in boiling, and when dished up it would take an expert to tell whether they were Cabbages or Savoys. In this particular, and most important it is, our little favourites are vastly different, as they retain their appearance throughout, and their flavour is at all times distinct and pleasing, or, indeed, all that we need ever expect Brussels Sprouts to be. The Dalkeith and the Rosebery varieties are the only real Brussels Sprouts I have, and I am so proud of the quarters of these that I possess that I shall save seed and try and keep them true.—A KITCHEN GARDENER.

RHODODENDRON TRIFLORUM.

THIS is a rare and very curious species, discovered by Sir J. D. Hooker in Sikkim, Himalaya. The colour is yellow, and the florets are not unlike those of *Azalea pontica*. The habit of the plant, however, is evergreen, and the backs of the leaves are profusely sprinkled with

Fig. 55.—*Rhododendron triflorum*.

scales, bringing it more into affinity with *R. ciliatum*, *glaucum*, and *cinnabarinum*. It seldom flowers as a small plant, which is a drawback, but, on the other hand, it is perfectly hardy, blooming too late in the season to be affected by the spring frosts. Two years ago I had a bush 4 or 5 feet high, which was covered with its triple yellow flowers, and excited much curiosity and interest. I have furnished many botanical gardens, with specimens, as well as my friends, Miss Jekyll of Munstead and Mr. Acton, a great *Rhododendron* fancier in Ireland. When the plant of the latter bloomed he wrote to express his delight on finding Sir Joseph's plate of this flower, which he had often wistfully, but hopelessly contemplated, at last realised in his own garden.

I have made many experiments for the purpose of hybridising this *Rhododendron*, but with little success. Some seedlings between it and *R. glaucum* are, however, coming on.—J. H. MANGLES, *Valenwood, Haslemere*.

FLOWER SHOW SCHEDULES.—I deny Mr. Wood's assertion, on page 204, that "I knew of the existence of 'The Eastbourne Gardeners' and Cottagers' Society' previous to receiving their schedules." On receiving the schedules I wrote to the Secretary, asking him if they held meetings

at which papers were read and discussed, at the same time expressing a wish to become a member. I received an answer saying "That a resolution had been passed to the effect that anyone joining previous to their shows must pay a year's subscription as entrance fee." I consented to pay this fee, although I had doubts as to whether I should be able to show or not. I did show a little, which would not have been much more had I been a member. I do not know how the members came to the conclusion "that I had no intention of attending the meetings," as that was my "chief" reason for wishing to join the Society. Now, what I ask the members of this Society to do is this, "Throw open the Society, and let the country gardeners around Eastbourne share in the privilege of meeting and discussing horticultural subjects; and if they continue to hold exhibitions, still reserve classes for members residing in Eastbourne."—J. GORE.

UNPRUNED FRUIT TREES.

IN February, 1881, I was directed to plant a piece of ground with Plum trees for kitchen use alone, using my own discretion as to the variety and style of tree. I decided to plant only one variety—*Victoria*, and to have standard trees tall enough to allow a crop of small fruit to be grown beneath. The soil was moderately heavy, 6 inches deep, and resting on clay, but very well drained. I had an offer of a few cartloads of night soil and ashes. This was trenched in, and in the operation a good depth of clay brought to the surface, and in this with a barrowload of good soil to each the trees were planted, their tops simply being shortened; they grew freely and made very strong shoots by the end of the season. The knife was not used, not a twig being touched. In 1882 they grew very strongly again, spreading out pretty regularly in all directions and forming good-sized heads. In 1883 a few fruits were had, but still they grew so strongly that I was often advised to root-prune them. I did not take that advice, and am glad that I did not. I have examined them rather closely to-day, and find that nearly all the wood made prior to last year is covered with fruit buds or spurs, in some places so thickly as almost to touch each other. Some of the trees have eight main branches, and out of these side branches grow at regular intervals, and with a little tying out they will make really handsome trees. On several branches about 2 feet long grown in 1882 I counted from twenty to thirty clusters of fruit buds, and if we are favoured with suitable weather when the trees are in bloom we shall have an enormous crop of fruit.

With Apples and Pears the result is the same. Some young Apple trees were planted about four years ago, and have never been pruned; the result is, the formation of fruit spurs on all wood made prior to last year; and on old bush trees that had been closely cut in for years but have lately been allowed to grow more naturally the same result is seen. Even Gooseberries are all the better for having part of the new wood annually left in. Nearly twenty years ago, when serving in a large garden, I noticed on Gooseberry trees trained to a north wall that new wood annually nailed in bore fruit its entire length, and yet the bush trees were yearly divested of nearly all young wood when there was plenty of room for it to remain. I am well aware that pruning cannot be altogether dispensed with; what I contend for is that pruning is like many other good things, it has been overdone, and it is time a more common-sense plan was adopted. I have been experimenting as far as my very limited opportunities would allow for several years now, and am satisfied that spur-pruning is a mistake as applied to hardy fruits not growing on walls. I have within the last few months had the pleasure of reading Mr. Simpson's useful book on the pruning and training of fruit trees, and, with respect to hardy fruits, my own experience fully confirms the views advanced in that work. I hope shortly to apply the principles of extension to Peach trees under glass than I have yet been able to do.—T. A. B.

AGAINST PLUNGING PLANTS IN POTS.

Do we not too often attach more importance to providing bottom heat than the circumstances of the case warrant? For my part I have long been under the impression that hotbeds in forcing houses for affording bottom heat are by no means indispensable; in fact, as I have frequently observed, they may easily prove injurious to many plants that may be plunged in them. If we were contented with standing the pots on the levelled surface of the hotbeds the case might be different, but plunged they may easily be overwatered, or even not get enough water, the former being the most fatal in its consequences. Then, again, the beds may suddenly become too hot, and either burn the roots or injuriously affect the unoccupied soil of newly potted plants, or, as more often happens, the heat declines considerably lower than desirable, and it is then when overwatering does much harm.

There may be causes where plunging material and a strong bottom heat are necessary adjuncts to the successful culture of plants, notably the Pine Apple, but I am by no means convinced of this even.

admit that when plants are first plunged in moist hotbeds they root and grow rapidly, much more so in fact than if stood on the surface only, but the gain is not so material as at first sight appears. Vines in pots, Melons, Cucumbers, Figs in pots, as well as many flowering and fine-foliaged plants, are apparently greatly assisted by bottom heat such as may be generated by a mixture of leaves and stable manure; but after all for various reasons it would have been better if less rapid or more woody growth had been formed, especially seeing what a check they experience when withdrawn from the beds, or if the bottom heat materially declines.

If we want short jointed well-ripened Vines we do not plunge the pots, well knowing that those plunged form larger but much softer and more pithy canes. Hundreds, I may say thousands, of Melon plants are annually grown to no good purpose, simply because they receive strong bottom heat at the outset, this declining most injuriously, at a time too when root heat is most necessary to assist in swelling and ripening the fruit. It is just the same with Cucumbers, only these are less liable to canker than Melons, besides yielding a fair crop before they collapse. Instead of taking a pride in having great leaves and large stems we ought rather to be satisfied with medium-sized healthy leaves and smaller and more woody stems, these being better calculated to withstand any strain or trial to which they may be subjected.

I hold that the roots require no more coddling than do the stems and leaves, and that plants can be forced into bloom, or started into active growth, and will fill the pots with roots quite as well as if they were plunged. Even the chambers formed over bottom-heat pipes are not unfrequently wasted, especially when a depth of plunging material is placed over them. I am aware that these chambers get very hot, but in many cases it is only because the materials over them have become very dry and non-conducting, the heat from the pipes thus being really wasted.

Let every pot and every mound of soil for Melons and Cucumbers be disposed on the surface of beds or on benches, and let the heat from the hot-water pipes, of which there should be plenty, serve for both top and bottom heat. At the very least the heat of the soil in the pots or mounds will never fall lower than the temperature of the house, and will share in the natural heat we secure on bright sunny days. The best crops of Melons I have ever seen grown, and the heaviest crop on Vines in pots I have ever seen, and which I assisted to grow, never received any assistance in the way of so-called bottom heat; and further, I have ripened Montserrat Pine Apples heavy and perfect in every respect, that were started and finished without bottom heat other than that afforded by the pipes under the bench on which the plants stood. Too few pipes in a house is the reverse of economical, and to enclose part of these in order to provide bottom heat, this necessitating making the top heating pipes unbearably hot, is in my opinion a great and common mistake. It is better by far in such cases to provide latticed stages or iron gratings for the plants or heaps of soil to rest on, and let all the pipes be moderately heated only. When warmer weather is being experienced the dry heat from the pipes may prove both injurious and unnecessary, and to obviate this cover these stages or gratings with moss or short litter, and by keeping this regularly moistened the evaporation produced will prove most beneficial. Under this treatment more water will have to be given the plants whether fruiting or flowering, but then those in charge experience no difficulty in deciding when it should be given, and, what is of equal importance, the soil in the pots will not be spoilt by worms. The latter alone, where they are as lively as with us, are enough to make anyone avoid any plunging material that will harbour worms.

In propagating, again, plunging material is by no means absolutely necessary; in fact, we strike more cuttings on the surface of beds and benches than anywhere, these including all kinds of softwooded plants as well as Roses, Carnations, and Bouvardias. In every case, however, the pots, pans, or boxes are kept at a safe distance from the pipes, and well shaded from bright sunshine.

I have quite as strong an objection to plunging pots in the open, especially in a cold moisture-retaining material. Roses, Carnations, and Chrysanthemums especially, all form better-ripened growth when the pots are unplunged, and this is better calculated to produce the best blooms during the winter. During very hot and dry weather a little light litter may well be strewed over the pots to prevent too rapid evaporation, and that is the only plunging material we find it advantageous to use.—W. IGGULDEN.

GIRTFORD GIANT RUNNER BEAN.—There is perhaps no season of the year more useful than the present for bringing under the notice of readers anything new or special amongst vegetables. General orders are no doubt in most cases made out, while in the case of new and apparently expensive seeds it often happens they are left to after-consideration. It is quite true much caution is necessary, yet every season convinces me more of the necessity to be careful, and not to be behind others in procuring anything that

is an improvement. This view was strengthened last season by the result of the trial of this Bean. I have long been a grower of this class of Beans, but the superiority of the Girtford Giant over others was remarkable, not only in appearance but in quality. In fact so much so that the others were much neglected by gathering so freely from this variety. So uniform and handsome were they that at our harvest festival we used them in clusters in a line amongst corn and fruits with great effect, and would advise any who have not given it a trial to do so.—E. B.

VINE ROOTS—MANURING VINES.

To make it clear to all of us you will allow me to say, perhaps, that I put quite a different construction on Mr. Thomson's words on the "Root culture of Vines" than is conveyed in a reply to a correspondent on page 236 last week. The writer of the latter says that "Mr. Thomson takes care to provide the roots before he gives top-dressings, and this is what everyone should do who desires a heavy crop of fine Grapes." Mr. Thomson, on the contrary, said, "Naturally the roots have the instinct of going where they have most to feed upon," and he recommends top-dressings to be applied from the beginning, and before the roots are produced, with the very object of creating them. "The moisture and elements of nutrition in the surface dressing will attract the roots," he writes; and speaking of top-dressing with "loam and horse droppings," &c., in autumn, and adding artificial manures in spring, he continues, "if this process is repeated every season it will keep the roots at the surface in the greatest health and activity." It is stable manure Mr. Thomson withholds, not artificial manures, which he says may be applied instead "at the first," at least I apprehend the words "bones and other appropriate manures" mean artificial manures. The note to a correspondent advises no artificial manures to be given till it is seen where the roots are. For my own part I make no distinction between artificial and other manures for the Vines, as both are applied for the same purpose. In brief, Mr. Thomson applies top-dressings to the surface of Vine borders to bring roots there and keep them there. I am not going to discuss the merits of the two systems, but I noticed Mr. Thomson's article at the time because it inculcates the principle that a rich soil produces roots sooner than a poor one. "At all events," says Mr. Thomson, "the roots of Vines can be led to multiply themselves at the very surface of the border" by the means he states. It will be remembered that not long ago it was stated that certain noted Vine borders had been filled with roots because of the poverty of the soil, so that you will see there are two quite opposite opinions entertained on the subject, one side maintaining that the way to do is to give poor soil first to produce mouths and feed afterwards, and the other, like Mr. D. Thomson, advising rich compost to be used for the same purpose. I agree with the latter.—CASUAL.

[We are always obliged by letters that add usefully to any instructions that appear in our columns, and the above communication affords us the opportunity for explaining that the sentence relative to "providing roots before giving top-dressings" had reference solely to artificial manures, and not to loam and stable manure. This qualification was not needed for the purpose of the inquirer who sought for information, as his letter had reference to artificial manures only. With that explanation we have nothing to withdraw from our remarks on top-dressing Vine borders in the answer under notice. We could add much on this important subject, but for obvious reasons we are unable to print an exhaustive essay in the brief space at disposal for answering inquiries.]

The point of our advice was and is that it is practically of no use applying artificial manures to those portions of a Vine border which contain few or no fibrous roots. There are hundreds of Vine borders at the present moment in that state, and if hundreds of pounds worth of artificial manures were spread on them the bulk of the money would be thrown away so far as regards the Vines, which would not be appreciably improved, though the soil over the fibreless roots would be made richer.

Artificial manures spread on the surface of a Vine border that contains only strong fibreless roots will not incite the emission of fibres from those roots and attract them through a mass of soil 1 or 2 feet thick, therefore the manure is wasted because it cannot be appropriated by the Vines; but if the soil be removed down to the black roots, and these are covered with a top-dressing of sweet enriched loam, containing also gritty matter such as wood ashes, and this is kept uniformly moist by a mulching of manure, then fibrous roots will form readily, and a million mouths be provided for appropriating the food that may be afterwards given where there were not a hundred before to absorb it.

Mr. Thomson's advice to "Apply loam and horse droppings in the autumn, and add artificial manures in the spring," is exactly in accordance with our views on this subject; and we are convinced if he advises the application of artificial manures "at the first," he presupposes the existence of fibrous roots not very far from them ready to turn the food that is given to profitable account. Much of the soil overlying the main fibreless portions of Vine roots is either so close and adhesive on the one hand, or so light and dry on the other, that it acts as a deterrent to the emission of fibres, and we consider the first duty of the cultivator is to remove such soil and add fresh, as it is vain to hope that it can be brought into the best condition for the Vines by the addition of artificial manure to the surface, however good the fertiliser may be.]

CRANSTON'S NURSERY SICK FUND.

THE first year of the establishment of Cranston's Nursery Sick Fund having expired, a general meeting of the *employés* was held in the seed ware-

house at King's Acre, on Thursday, 20th March, 1884, John Cranston, Esq. (President) in the chair, the vice-President, Hugh Ronalds, Esq., being also present. The whole of the *employés*, numbering upwards of 100 men and lads, attended. The Chairman congratulated all present upon the success of the undertaking, which he described as far exceeding the expectations of the promoters, attributing that success to the very general unity which he was so pleased to see existed amongst all concerned. Having in a few well-chosen words given all present some excellent advice regarding thrift, and the importance of making some provision against sickness, he called upon the Honorary Secretary (Mr. J. T. Mayo) to read his report, which was received and adopted as read. It was then arranged to pay a bonus to each, to the amount of one-half their contributions; this will reduce the amount in hand by £14 14s. 7½d.; the balance, £7 10s. 7½d., to be placed to a reserve fund. It was further agreed to increase the weekly allowance in case of sickness, from 5s. to 8s. for men, and from 2s. 6d. to 4s. to boys, during the first six weeks of their illness, and, should they still continue ill, half that amount for the next six weeks, after which they will not be entitled to any benefit for the next twelve weeks. The contributions to remain the same as heretofore—viz., 2d. per week for men and 1d. per week for boys, which amount is deducted (in advance) once in every three weeks from their wages, an arrangement to which all very readily agreed to without a single dissentient. The allowance in case of death has also been increased from £1 to £2 10s., and the widow of one of the late *employés* has just been paid this latter sum, he having died two days after this alteration was made, after an illness extending over six weeks. His total contributions amounted to 9s. 4d., whilst he and his widow have benefited to the amount of £3 16s. 4d., which clearly demonstrates the great amount of good which can be done by workmen combining in this way. The general regret expressed among the men here is that it was not established years ago.

The subscriptions during the year amounted to £40 12s. 10d., of which £15 14s. 7d. was paid to sick members, £2 13s. refunded to *employés*, leaving the remaining £3 5s. 9d. in expenses of management, the balance being disposed of as above mentioned.

At the conclusion of the business a hearty vote of thanks was accorded Mr. Cranston for presiding, also to Mr. Hugh Ronalds. In responding, Mr. Cranston promised to give all the *employés* a day's holiday during the first week in June, with which all were delighted. Three hearty cheers for Mr. and Mrs. Cranston, and Mr. and Mrs. Ronalds, with a cordial vote of thanks to Mr. J. T. Mayo, the Hon. Secretary and Treasurer, brought this most successful meeting to a close.—H. R. ILLMAN, *King's Acre, near Hereford*.

At a general meeting of the ROYAL HORTICULTURAL SOCIETY held yesterday, William Houghton, Esq. (Treasurer), in the chair, the following candidates were unanimously elected Fellows, viz.:—William Poile Cockburn, Miss de Maine Constantine, Miss Egginton, Frederick C. Jacomb, J. Stanley James, George Jarrett, Mrs. Milner, Julius Newton, George Pounce, Baron Schroeder, Charles Henry Sharman, Edward A. Wallace, Walter H. Williams.

— WE understand the next Show of the WIRRAL ROSE SOCIETY will be held in St. George's Hall, Liverpool, on Friday, the 11th July next.

— FOR a period of three weeks that handsome shrub FORSYTHIA SUSPENSa has been flowering in a few suburban gardens, and its blooms are still fresh, bright, and abundant. F. viridissima is better known than this species, but it is much inferior in attractions, and it is difficult to understand how the superior form has been so much neglected. Richer in colour than the old and well-known Jasminum nudiflorum, with fine bell-like flowers three or four times as large, and equally profuse, there can be no question as to which is the better species in a horticultural point of view.

— A LIVERPOOL correspondent writes:—"We have been having changeable WEATHER recently. The temperature was 70° in the shade on Sunday the 16th inst. On Thursday the wind was piercingly cold. Some of the early Pear trees are in full flower. One frost which is sure to come will, I fear, blight all hopes of a crop on early varieties. Apples are keeping back wonderfully well. Hyacinths in a few days outside will be in full beauty, and Daisies are growing and blooming as if at the end of April."

— A CORRESPONDENT recommends the following as useful and beautiful varieties of GHENT AZALEAS—Magnifica, pontica sulphurea, pontica magnifica, Marie Dorothée, pontica tricolor, Triomphe de Ronquern, monstrosa fascicularis, Van Dyck, Admiral de Ruyter, elegans Optima, and Exquisite.

— ALTHOUGH at the present time Amaryllises command primary

attention in MESSRS. VEITCH & SONS' NURSERIES AT CHELSEA, they after all only form a share of the attractions. The Hyacinths are magnificent, and with other flowers in the same house—Rhododendrons, Cinerarias, bright and sturdy; Azaleas, Cytisuses, Gueldres Roses, &c.—form a display of remarkable beauty, and well worthy of inspection. One or two plants particularly noteworthy are the following:—

— RHODODENDRON SUAVE.—This is stated to be the result of a cross between R. Edgworthii and R. ciliatum; it has stout woolly leaves, resembling those of the latter, and pure white flowers 2 to 2½ inches in diameter, and as sweet as the Honeysuckle. On this account, as well as the dwarf sturdy habit of the plant, Rhododendron suave must be regarded as an acquisition to the [great and beautiful family to which it belongs.

— AZALEA AMENA CALDWELLI.—The merits of this early and effective variety are not sufficiently known. It has the same small foliage, compact habit, and floriferous character as the species, and the flowers are similar in colour, but twice or thrice the size, which renders the plants particularly striking. For conservatory decoration in winter and spring the variety under notice is invaluable.

— WIGELA HORTENSIS NIVEA.—This is evidently admirably adapted for forcing, presuming that the wood is well ripened in the summer. It is now flowering freely, and not many plants in the house are more chastely attractive, which the sprays when cut must be amongst the most acceptable for various decorative purposes.

— ORCHIDS.—There is quite a wealth of flowers of these, and ever-arriving importations of plants render increased accommodation imperative; hence a new house, and a very fine one, is being erected for Cattleyas by Messrs. Weeks & Co. This house is 130 feet long by 22 feet wide, with a lantern roof with ventilators. It is a span-roofed structure, with side lights 2½ feet high on walls of the same height, with sliding ventilators in them. Tanks are provided in the centre of the house, and twelve rows of 4-inch pipes are provided for heating, this liberal provision preventing the necessity of having the water very hot, thus affording a genial temperature and saving fuel. This is a very superior structure in every respect, and will maintain the reputation of the builders.

— IN the paragraph (page 207) announcing a paper on THERMOMETERS by Robert H. Scott, M.A., to be read at a meeting of the Royal Meteorological Society, the date was, by the Secretary's mistake, given as "Wednesday the 21st inst.," whereas presumably the 19th inst. was intended. The *Gardeners' Magazine* in drawing attention to this remarks—"It strangely happens that they have forgotten to state in what year the event may be expected to take place." We appreciate our contemporary's acuteness, but unfortunately in another column of the same issue "the event" is announced with no indication whatever as to when it is, or was, "to take place."

— A FLORIST writing on DOUBLE PRIMROSES remarks:—"We have the old double crimson-velvet, blush, white, lilac, carmine-rose yellow-crimson, and purple, all perfect rosettes, and very beautiful. Many are lost in gardens through being left undisturbed, as they form a woody stem out of the ground, and the young roots perish as they grow out from the stem through not having soil near them to run in. We find them succeed best in a sheltered nook. They are taken up annually in the autumn, the larger clumps are divided, and are replanted in good loam with a little leaf soil, pressing the soil round the collar of the plant. Treated in this way they form good flowering plants by the spring."

— POTATOES are this season unusually abundant and cheap, large quantities being offered as low as £4 10s. per ton, and some at even lower prices. They are also generally very sound, scarcely any disease being perceptible. A correspondent in referring to the low prices being realised this year for Potatoes of first-rate quality, remarks that he has in some years at this time obtained as much as £10 per ton for Potatoes much inferior to those he is now selling at £4 to £5.

— THE well-known fragrant, sweet-scented LEMON VERBENA (Lippia citriodora) is regarded among the Spanish people as a fine stomachic and cordial. It is either used in the form of a cold decoction sweetened, or five or six leaves are put into a teacup and hot tea poured upon them. The author of a work, "Among the Spanish People," says that the flavour of the tea thus prepared "is simply delicious, and no one who has drunk his pekoe with it will ever again drink it without a sprig

of Lemon Verbena." And he further makes a statement, more important than all the rest, if true—that is, that if this decoction be used, one need "never suffer from flatulence, never be made nervous or old-maidish, never have cholera, diarrhoea or loss of appetite."

— THE WOLVERHAMPTON HORTICULTURAL SOCIETY will hold their annual Show in Col. Thorneycroft's grounds at Tettenhall, Wolverhampton, on July 14th, 15th, and 16th of the present year. Classes are provided on the schedule just issued for plants, flowers, fruit, and vegetables, many being open to any exhibitors.

— MR. R. S. BAXTER writes:—"The following NYMPHÆAS ARE NOW FLOWERING IN THE OXFORD BOTANIC GARDEN:—*N. Daubeniana*, the most useful variety for early and late flowering. It is of an azure blue colour suffused with lavender, and is very fragrant. It produces young plants from the centre of the leaves, and these if allowed to remain on the plant also produce a number of small flowers about the size of Daisies, which have a pretty appearance floating on the water. *N. cyanea*.—This also is a very free-flowering species, producing a great number of blue flowers. *N. scutifolia* differs from the above, being of a darker blue than the two former, and the petals being broader; it is also very fragrant. We have also the *Lymnocharis Humboldtii* and the *Eichornia azurea* in flower, showing the advantage of keeping aquatics in water all the year round, and reducing the temperature in winter to 60° or 62°. The tubers should be planted in tubs in some heavy loam, and a little manure placed in half the depth."

— THE usual monthly meeting of the HORTICULTURAL CLUB was held last Tuesday; Professor Michael Foster, F.R.S., and Mr. F. E. Stumfel were elected members.

— AS has been previously announced, valuable prizes are offered for fruit and vegetables by the ROYAL HORTICULTURAL SOCIETY at South Kensington during the ensuing season. The schedule of prizes is now being issued, and it appeals temptingly to cultivators far and near, as good prizes are offered for single dishes of the different kinds of fruit, which can be so easily transmitted, also for dishes of vegetables. When we find prizes of 15s., 10s., and 7s. 6d. for six bunches of Radishes, it can no longer be said that vegetables are ignored. Excellent prizes are also offered for collections of fruit and vegetables throughout the series of shows which are to be held in May, June, July, August, September, and October. At the Cottagers' Show in August we find a distinct and most commendable innovation in the form of a series of prizes ranging in value from £5 to 10s. 6d. provided for competition amongst the various local Horticultural Cottage Garden Societies and allotment holders in the country, the Secretary of each Society, or other authorised person, collecting the produce for exhibition. The schedule, which should be widely distributed, is a very practical and excellent production, and undoubtedly creditable to the compilers.

— MESSRS. CARTER & Co. have sent us examples of PURPLE SPROUTING BROCCOLI, numbered 1 and 2. The latter is a good example of the ordinary type, the former having much greater density of inflorescence, and with comparatively few leaves, resembling somewhat a rather loose, tall, pyramidal-shaped Cauliflower. The two examples before us are very dissimilar.

— WE learn from the schedule of the NORTHAMPTONSHIRE HORTICULTURAL SOCIETY that at their annual show, to be held in Delapre Park, August 4th and 6th, a prize of a very novel character will be offered by Mr. John Edward Perkins, Billing Road Nurseries, Northampton. This is the first prize in Class 9, for a group of miscellaneous plants for conservatory decoration, arranged for effect in a space of 26 by 12 feet, and consists [of a life membership of the Gardeners' Royal Benevolent Institution, value ten guineas. Such a handsome and useful prize may be expected to bring a number of competitors, and so excellent an example might be advantageously followed by other donors of special prizes. Very liberal provision is made in the numerous other classes at this Show, the prizes ranging from £12 to 1s. for plants, flowers, fruit, and vegetables. The third Seedling Potato Exhibition will be held in the Town Exchange, Northampton, on September 24th and 25th, when four classes will be provided, four prizes in each, value £1 10s. to 5s.

— GARDENING APPOINTMENTS.—Messrs. John Laing & Co., Forest Hill, inform us that the following appointments have been recently

made through them. Mr. Wm. Crump, lately at Beaurepaire Park, Basingstoke, Hants, as head gardener to J. P. Currie, Esq., Sandown House, Esher; Mr. McDonald as head gardener to R. Johnstone, Esq., Boulogne-sur-Mer, France; and Mr. Jas. Taylor, lately gardener at Storrington Rectory, Sussex, as gardener to J. Patrick, Esq., Hunstanton, Norfolk.

— WE have received Part 2 of Messrs. Cassell's "ENCYCLOPÆDIC DICTIONARY," which carries the work up to the word "Alder" in this excellent work.

— THE monthly general meeting of the members of the NOTTINGHAMSHIRE HORTICULTURAL AND BOTANICAL SOCIETY was held at the Mechanics' Institute on the 20th inst., when Mr. C. E. Pearson of the Chilwell Nurseries delivered a very interesting lecture upon garden insects. The chair was taken by Alfred Page, Esq., and there was a large attendance of gardeners and others interested in horticulture. Mr. Pearson, who takes a great interest in the Society, and who is very popular amongst the members, said he would divide his lecture into two parts, and would first deal with those insects which were inimical, and secondly with those which were friendly to the horticulturist. He spoke of the aphid as a very destructive insect, and its remarkable powers of reproduction. He next referred to the formation and habits of the caterpillar species, and said it was much to be regretted that gardeners did not sufficiently study entomology, but destroyed indiscriminately both friends and foes. He next dealt with the great order of beetles, and pointed out their destructive powers. The earwig, the ant, the cricket, slugs, snails, woodlice, red spider, mealy bug were next very ably dealt with by the lecturer, who at the conclusion of his lecture was very warmly applauded and accorded a very hearty vote of thanks. There were in the room many excellent specimens of flowers and plants which were sent by the members of the Society, amongst them being a variety of Dendrobiums and other cut Orchid blooms, sent by the Vice-President of the Society, S. Thacker, Esq.; fine pots of Strawberries, sent by Mr. Gennan, gardener to T. B. Cults, Esq., Malvern House; a splendid basket of Roses from Mr. Walker, gardener to J. W. Lewis, Esq., Hardwick House. Col. Seeley, M.P., Sherwood Lodge, sent a fine plant of Cyclamen Rosy Morn, which was much admired. Mr. Edington, Woodthorpe Grange, had some remarkably fine cut blooms of Gardenias.

LIVERPOOL HORTICULTURAL ASSOCIATION.

MARCH 19TH.

THE Exhibition held in St. George's Hall on Wednesday last is the second under the auspices of the above Society, and proved a great success as far as the exhibits and the weather were concerned. It is a question if the hall ever presented at this season of the year such a gay appearance, for it was crowded with Hyacinths and other spring-flowering plants. Many pronounced the Exhibition the finest ever held in Liverpool. The local nurserymen—Messrs. R. P. Ker & Sons, the Horticultural Company, Garston, and Messrs. T. Davies & Co., Wavertree—have by their large and varied exhibits from time to time done much towards rendering the exhibitions of this Society successful, and their contributions to the Exhibition just held were large, varied, and attractive.

HYACINTHS IN POTS.—These throughout were well represented, and the prizes offered were well contested for. Some fine blooms were staged, but, taking them as a whole, they were not quite equal in quality to those of last year. In the class for eighteen distinct varieties five collections were staged. Mr. W. Mease, gardener to C. W. Newmann, Esq., Wyncote, Allerton, was well to the front with well-grown examples. The plants were even, the spikes good, and the foliage remarkably dwarf. His best were—whites: Baroness Van Tuyll, good; Grandeur à Merveille, Mont Blanc, fine. Reds: Von Schiller, Koh-i-Noor, very good; Emmeline, grand bells; Lord Wellington, double. Dark blues: Baron Von Tuyll, Marie, Sir Charles Napier, King of the Blues. Light blues: Charles Dickens, Ozar Peter, and a fine spike of Ido, yellow. Mr. J. Kelley, gardener to R. Singlehurst, Esq., Endfield House, Aigburth, was second with fine spikes, but slightly drawn, Mr. J. Phythian, gardener to D. Walker, Esq., Forest Lawn, West Derby, securing the remaining prize with good examples. In the class for twelve varieties seven collections were staged. Mr. Kelley took the lead with handsome plants, the flowers being very fine, but slightly drawn as in his second-prize collection; they, however, included a wonderful specimen of King of the Blues. Mr. J. Wilson, gardener to J. E. Reynolds, Esq., Sandsfield Park, West Derby, was a good second. Mr. E. Cropple, gardener to T. S. Rogerson, Esq., The Priory, St. Michaels, followed with very creditable plants. For six Hyacinths Mr. G. Bennett, gardener to L. S. Abbott, Esq., Dosoris, St. Michaels, was deservedly placed first, followed by Mr. A. R. Cox, gardener to W. H. Watts, Esq., and Mr. E. Green, gardener to J. Woolwright, Esq., Mossley Hill, six or seven collections being staged in this class.

NARCISSUS.—The schedule only contained one class for these, but seven collections were staged for the three prizes offered for six pots, not less than three varieties. They were all in good condition, especially those shown by Mr. W. Mease, who was awarded the premier position for good, dwarf, well-flowered specimens of Bazelman Major, Mont Blanc, Soliel d'Or, Grand Primo, and La Parfaite. Mr. J. Jellico, gardener to F. Gossage, Esq., Camp Hill, Wootton, was second, having good Gloriosa, Mont Blanc, and Belle Aurora; Mr. E. Green being placed third.

TULIPS.—These throughout were a magnificent display, and in the very best of condition. For twelve pots, six varieties, Mr. W. Mease was to the front with grand examples of Keyzers Kroon, Rose Pepin, Vermilion Brilliant, Louis d'Or, Joost Van Vondel, and Globe de Rigaud. Mr. T. Stephenson, Park House, Waterloo, was a good second, and had good Rouge Luisante, Grand Duchess, and Grand Duc de Russie. Mr. W. Minshull, gardener to H. Nash, Esq., Ullet Road, was third. For six pots Mr. E. Green took the lead with good White Pottebakker, Keyzers Kroon, and Couronne Cardinal. Mr. C. Copple and Mr. J. Lowndes, gardener to S. S. Parker, Esq., Woodlands Road, Aigburth, were second and third. For ten pots of double varieties, not less than five distinct kinds, Mr. W. Mease was again successful, having good Golden Tournesol, Tournesol, Couronne des Roses, and Cochenelle; Mr. T. Stephenson second, and Mr. W. Evans, gardener to Mrs. Lockett, third, the last collection being a little uneven. For six pots Mr. James Hurst, gardener to W. B. Bowering, Esq., was the successful competitor. Mr. W. Bustard, gardener to J. Lewis, Esq., St. Anns, Aigburth, was awarded a first prize for pots of Crocuses, his collection being the only exhibit in that class. The schedule provided one class for Amaryllises, and Messrs. W. Mease, W. Bustard, and J. Hurst were the prizewinners.

STOVE AND GREENHOUSE PLANTS.—Though by no means numerous, the plants staged reflect the greatest credit upon the exhibitors. In the class for six, three in flower and three fine-foliage, Mr. Mease was the most successful, having a noble plant of *Latania borbonica*, *Croton Williamsii*, and *Croton Disraeli*, very fine plants; *Rhododendron Victoria Regina*, 5 feet high and 3 feet through and covered with light yellow blooms, was very conspicuous, and the same may be said of his plant of *Imantophyllum* *miniaturum* maximum, a grand form of this useful and showy plant. His other plant was a large well-flowered specimen of *Azalea Bernard Andreas*. Mr. A. R. Cox was placed second, the fine-foliage plants in this collection being good, while the three flowering plants were weak. For one stove plant in flower the same exhibitor was first with a large profusely flowered plant of *Clerodendron Balfourianum*, wonderfully fine for the season. Mr. J. Jellico was second with a well-flowered *Phaius grandifolius*. In the corresponding class for one greenhouse plant Mr. J. Lowndes took the lead with a large *Chorozema cordatum splendens* flowering freely. Second Mr. J. Stephenson, gardener to Mrs. Horsfall, Grassendale Priory, with a noble plant of *Imantophyllum* *miniaturum*; and third Mr. M. Wood, gardener to Lieut.-Col. Wilson, The Hermitage, St. Michaels, with the same variety. For one foliage plant Mr. Mease was first with his large plant of *Croton Weismanni* 7 or 8 feet through; Mr. A. R. Cox second, and Mr. W. Evans third, both staging healthy specimens.

PALMS AND CYCADS.—These were very well represented, and the plants generally were large and healthy. In the class for three plants Mr. T. Jellico was placed first with large but not the most healthy plants. Mr. S. Whitfield, gardener to J. T. Cross, Esq., Beechwood, Aigburth, was second with a little smaller but very healthy plants of *Phoenix rupicola*, *Latania borbonica*, and *Areca sapida*. Mr. E. Thrupp, gardener to Mr. Walmsley, Westwood House, Wigan, third, having a good *Cycas revoluta*. For one plant Mr. S. Whitfield was deservedly first with a very large specimen of *Kentia australis* in the best possible condition. Mr. J. Hurst following.

FERNS.—The competition in the classes devoted to these plants was keen, and the plants staged were large well-grown specimens. Mr. J. Stephenson took the leading position for four plants with *Davallia Mooreana*, large; *Alsophila Moorei*, *Adiantum formosum* fully 5 feet through, very good; and *Gymnogramma chrysophylla*. Mr. J. Phythian second, having a plant of *Adiantum excisum* 3 feet through, and a fair *A. farleyense*; Mr. A. R. Cox being the remaining prizetaker. For one plant Mr. W. Evans was first with a wonderful specimen of *Goniophlebium subauriculatum*; Mr. Jellico second with a large plant of *Davallia Mooreana*; and Mr. S. Whitfield third with a similar plant to that shown by the first-prize winner, but not quite so large.

The prizes offered for a group of miscellaneous plants arranged for effect, not to exceed a space of 50 square feet, arranged in semicircular form, only brought one exhibitor, Mr. W. Mease, who staged a very neat collection of small flowering plants.

TABLE PLANTS.—At this Society's exhibitions table plants are generally well shown, and on this occasion six or seven competitors entered in each class. The plants throughout were small and neat. For six Mr. J. Agnew, gardener to Mrs. Watts, Grassendale Park, was placed first. His best plants were *Croton interruptus aureus*, *C. Chelsoni*, *Cocos Weddeliana*, *Pandanus Veitchii*, and *Dracaena Guilloylei*. Mr. M. Wood was second with a good *Dracaena Cooperi* and *D. gracilis*; and Mr. A. R. Farrington, gardener to Mr. Gilbert Park, Mariebonne, Wigan, third. For three plants Messrs. E. Thrupp, C. Copple, and W. Bustard were the prizetakers in the order named.

AZALEAS.—These were an attractive feature of the Exhibition, and displayed a marked improvement over those staged last spring both in the size and condition of the plants generally. Three collections were staged in the open class for six distinct varieties. Mr. W. Evans took the lead with large profusely flowered pyramidal plants not named, followed by Mr. W. Mease with very much larger plants, but not so well flowered, except plants of *Flower of the Day* and *Grandis*. Mr. E. Green was third. For three plants four competitors staged, and the premier position was accorded Mr. W. Mease for profusely flowered large plants of *Souvenir de Prince Albert* and *Reine des Belges*. Mr. J. Lowndes was second with good *Stella* and *Queen of Beauties*; and Mr. J. Hurst third, having a well-grown plant of *Flag of Truce*. For one plant the successful exhibitors were Messrs. J. Lowndes, T. Gowan, gardener to — Cunningham, Esq., Mossley Hill, and Mr. W. Mease. For four plants in pots not exceeding 8 inches in diameter Mr. Gowan was again first with neat well-flowered plants, the blooms being of large size. The varieties were *Bernard Andreas*, *Princess Alice*, good; *Appollon*, and *Hercules*. Second Mr. W. Evans, with a little larger plants well bloomed, but the flowers were much smaller than in the first collection. Third Mr. E. Green with rather looser specimens. For six plants of *Azalea mollis* Messrs. W. Bustard and W. Mease were the prizetakers, both showing compact bushes.

Cinerarias were all that could be desired, many of the plants having heads of bloom 2 feet or more over, and the plants not more than 18 inches high. The competition was good, eight lots being staged. Mr. J. Agnew took the lead, followed by Messrs. J. Stephenson and J. Wilson, the last having smaller but very dwarf plants with large flowers. *Primulas* were not

so good as we have seen them, the majority of the plants being large with small flowers.

Cyclamens, *Lily of the Valley*, and *Callas* were fairly represented in the various classes, the last-mentioned being particularly good; while the *Lily of the Valley* was very fine, the spikes of some of the examples being large and the foliage very rich. The principal prizetakers were Messrs. J. Jellico, Stephenson, W. Evans, G. Bennett, W. Mease, Wilson, and Copple.

Other forced plants added very much to the interest and beauty of the Exhibition. For six, Mr. Lowndes gained the first position with a good collection, including a good plant of *Azalea amoena*, *Azalea Appollis*, a beautiful yellow; *A. mollis*, *Rhododendron Vesta*, and *Deutzia gracilis*. Mr. Mease was second with a striking plant of *Rhododendron fragrans*, *Rhododendron Mad. Wagner*, and *Azalea amoena*. *Roses* were not numerous nor extra good. For twelve cut blooms there were two exhibits, the flowers were not large, but very creditable for this time of the year. Mr. A. Collins, gardener to S. Smith, Esq., Prince's Park, took the first award, and Mr. G. Park the second.

Only two collections of hardy herbaceous and bulbous plants were staged for the three prizes offered, and this is to be regretted, for nothing in the Exhibition created greater interest or attraction. Messrs. J. Dickson and Sons, Newton Nurseries, Chester, were accorded the premier position, and Mr. W. Meason second for a very neat and interesting collection. The most striking in the Chester collection were *Primula villosa nivea*, white; *P. Sieboldi*, good; *P. rosea*, *Narcissus laurifolius* Emperor, *N. bicolor* Empress, *N. odoratus*, *N. Trumpet Major*, *Mertensia virginica*, and *Iris Beauty*.

ORCHIDS.—The prizes offered for these popular plants were well contested for, and their delicate curious flowers attracted great interest, for the public crowded round them the whole of the day. Mr. E. Green took the lead for four plants, having a good *Phalaenopsis Schilleriana*, *Dendrobium chrysotoxum* with eight spikes of flowers, and *D. thyrsiflorum*, a fine plant with the same number of spikes, and a fair plant of *Cattleya Trianae* with nine flowers. Mr. J. Wilson was second with *Odontoglossum Alexandrae*, good variety, large spike, *Odontoglossum aureum purpureum*, *Dendrobium Wardianum*, healthy; and *D. nobile*, a well-flowered specimen. Third, Mr. J. Edwards, gardener to Shadford Walker, Esq., 88, Rodney Street, Liverpool, with *Dendrobium crassinode*, with seven flowering bulbs; *Cattleya Trianae*, five flowers; *D. Wardianum*, fair; and *Odontoglossum maculatum superbum*. For one Orchid Mr. E. Green was first with *Phalaenopsis Schilleriana*. Mr. A. Smith, gardener to D. de Yborrondo, second with *Dendrobium crassinode*, and Mr. R. G. Michie, gardener to E. L. Wigan, Esq., Sefton Park, third, having a good *Dendrobium primulinum*, fine form with four large-flowering pseudobulbs.

MISCELLANEOUS EXHIBITS.—Messrs. R. P. Ker & Sons, Aigburth Nursery, contributed a magnificent display of *Hyacinths* and *Tulips*, some 250 or 300 of the former. The same firm also had a group of that useful sweet-scented plant, *Choisya ternata*, and *Staphylea colchica* in very fine condition. The Horticultural Company (John Cowan), Garston, had about 100 plants of a dwarf large-flowered strain of *Cinerarias*. The plants were not more than 9 inches to 1 foot high, and the head of bloom nearly as much in diameter, many of the individual flowers being 3 inches over; they also staged a collection of foliage and spring-flowering plants associated together, and edged with *Adiantum Pacotti*. Messrs. Davies & Co., Wavertree, had a mixed collection of spring-flowering plants, which were highly effective and most creditable to them. Mr. A. Waterer, Knap Hill Nursery, Woking, staged a magnificent display of *Primroses* and *Polyanthuses* in pots, which were much admired; also plants of *Andromeda japonica* splendidly flowered, for which a certificate of merit was awarded. Mr. J. Gore, gardener to T. Holden, Esq., Ullet Road, a splendid plant of well-bloomed *Imantophyllum* *miniaturum*, and for which a cultural certificate was awarded. Mr. Wells staged his new *Violet Wellsianum*, which was highly commended, the Judges not thinking it sufficiently free for a first-class certificate. H. Holland, Esq., contributed a number of Orchids, and Messrs. J. Dickson & Sons a small collection of choice named *Auriculas*. Mr. James, the well-known grower of florist flowers, showed a collection of *Cineraria* blooms, principally selfs, which for shape and colour could not be surpassed. The arrangement of the Exhibition throughout reflected great credit upon the Chairman, Mr. Richardson, Mr. Gore the Secretary, and the Committee.

A NOTE ON RHUBARB—HAWKES' CHAMPAGNE.

It appears to me that Rhubarb as a garden crop has a peculiar position. By some gardeners it is talked about and treated with a half contemptuous sneer on the lip, as if it was just tolerated in the garden by reason of some fad of the owner's. By others it is grown anyhow in any corner, with a "Oh, it doesn't signify, it's only Rhubarb, you know" remark when spoken to about it; whilst there are gardeners who care for Rhubarb much, and who give large attention to it, both as to its cultivation and the many varieties there are in growth now-a-days. Rhubarb has also a peculiar position as to its own identity. With many it is erroneously considered to be a fruit, having, as it has, the juicy properties of fruit, and even in the minds of those who ought to know better, when these fruit properties are taken into account, there is an amusing amount of confusion as to whether it is a fruit or a vegetable. In America it is almost invariably called the Pie Plant, and the name is expressive. That settles the purpose at any rate, if not the position of Rhubarb. Commercially Rhubarb ought to occupy a good position in every garden. Its value in the market is great, and its value as a factor in the sum of the public health is greater still. Rhubarb coming freely into use in the critical spring months of the year has an influence on the health of the body politic which is worth more than a passing consideration.

Culturally Rhubarb is the easiest crop to grow of any in the garden. Deep well-manured soil, an open position, with the proper

varieties to grow, and a crop of this esculent is certain. The question of varieties to grow is an important one; it is really the reason why I am writing on Rhubarb now. Anybody can grow Rhubarb, but it is not everyone that can secure the variety or varieties to grow. I have been testing all the culinary varieties of Rhubarb that I could get now for a few years. I have also tried one or two varieties as to decoration, but that is not my subject at present, and I believe I should reduce the cooking Rhubarbs to three varieties. I put Hawkes' Champagne first for earliness, Johnstone's St. Martin's for general summer use, and Victoria for late work and for strong forcing purposes. Hawkes' Champagne is a fortnight before anything else; for instance (April 18th), this is 2 feet high. Johnstone's is 1 foot high, and Victoria is only just moving. Hawkes' is a beautiful Rhubarb too, such a good colour, and is in great demand by our cook for syrups and stewing purposes. This is not in the market yet I understand; but Mr. Gilbert of Burghley, who is never so happy as when giving to friends some good thing, sent it to me in quantity. Johnstone's is a very continuous bearer through the summer, and for large sticks for forcing nothing excels Victoria. I have forced Hawke's this year, and it is very pretty and good, but does not give very large sticks. It is a very good sort for all that, and it is to call attention to it that I write this note.—H., Notts.

RHODODENDRON VEITCHIANUM.

OWING to the number of fine varieties of greenhouse Rhododendrons which have been introduced to cultivation by Messrs. Veitch and others of late years, this fine species, which is of older date, has been somewhat neglected.

If cultivators of these plants could, however, see a specimen now flowering in the greenhouses at Oakholme, Sheffield, the residence of Thomas Wilson, Esq., they would, I believe, agree with me that it is one of the best ever introduced. The plant in question is trained over a stone wall with a south aspect, but is screened from the direct rays of the sun by a bank of large Camellias immediately in front. The space of wall occupied by the plant is 100 square feet, which at the present time is covered with large white and beautifully fringed blooms. I counted the expanded blooms and trusses. The number of expanded blooms was 195, of trusses 135, mostly of three blooms each, seventy of which were open and sixty-five still to open. I have sent you a specimen truss.

Mr. Hannah (Mr. Wilson's able gardener) has grown the specimen from a small plant 6 inches high, with a single shoot, thirteen years ago. For the first five years it was grown as a small plant in a pot. Eight years ago it was planted out in the position it now occupies in a border 1 foot deep, 1 foot wide, and about 4 feet long, which is bounded by the flagged pathway. The compost in which it is planted is fibrous peat, with a liberal admixture of silver sand. In planting it out Mr. Hannah bent its stem into somewhat the shape of the letter S to reduce its length of stem, and to that he partly attributes its remarkable floriferousness. I have known it almost from the time it was planted, and it has annually been covered with bloom.—W. K. W.

[A truss of three fine pure white and highly fragrant flowers accompanied this communication, and proved how well the plant is grown at Oakholme. This is an extremely handsome species and well deserves all that has been said in its praise. A wood engraving of a flower and foliage was given in this Journal, page 235, vol. xxxvi., March 27th, 1879.]

THE KEW ROCKERY.

For many years the only rockery at Kew was one of very moderate extent, and no pretensions to picturesque beauty, situated near the house devoted to economic plants. This served as an abode for a small collection of alpine plants, which succeeded fairly well, but were by no means representative in numbers of the multitudes of interesting and handsome species which the American, Asiatic, and European ranges of mountains have furnished to our gardens in recent years. The insufficiency of this, especially in a national garden, was long felt, and many efforts were made to provide more adequate accommodation for these plants, but without avail until about two years since, when a memorial was presented to the Commissioners on the subject, the result of which was that a sum of £500 was specially granted for the construction of a new rockery that should be a credit to the establishment, and permit a greater number of plants to be grown in suitable quarters. This was probably somewhat hastened by the large and valuable collection of plants bequeathed to the nation by Mr. Joad of Wimbledon, and consequently in February, 1881, the much-needed work was commenced.

The site chosen was the piece of level turf between the wall by the herbaceous ground and the Orchid house, which is about 500 feet long, and runs nearly due north and south. The subsoil being a light sandy gravel, no artificial drainage was required; and the general form of the rockery being determined upon, it was only necessary to remove a portion of the soil to the depth of about 6 or 7 feet below the general level, raising mounds on each side varying in height above the central path to from 6 to 12 feet. The path is 10 feet wide, and descending by a gradual slope from the north end, and ascending at the south extremity by a few steps winding considerably in its course, thus giving a great variety of aspects to accommodate plants of very diverse requirements. Some have considered it a defect in the construction of the rockery that the path should be for

the greater portion by its length quite level, but to have altered this in a suitable manner would have occasioned much greater expense than could be incurred at the time, and unless thoroughly done it would have been no improvement on its present form.

The stone principally employed is much-weathered boulders of limestone from Cheddar, some of which are extremely picturesque, worn and perforated, tufa, granite, sandstone, and some composition. With the exception of a few portions no attempt has been made to arrange the rocks in stratigraphical order, as the principal object was to provide nooks, recesses, and "pockets" of a fitting character for the plants, at the same time studying picturesque effect as far as possible. The background and highest portions are occupied with Rhododendrons and small specimen Box trees, behind these being a sufficient number of larger Conifers to afford some shelter without casting too dense a shade, and these improve the effect greatly.

Recesses or alcoves are provided at intervals and devoted to special plants, such as those abounding in peat districts, others growing in swamps, on the seashore, &c., all of which have their peculiarities carefully studied and suitable soils supplied. These constitute a series of highly interesting features, which are still further increased by the nooks of Daffodils, Lilies, Hellebores, and Primroses, which with many others yield a continual succession of flowers from early spring to late autumn. At the present time the Daffodils are in fine condition, while some fine clumps of Polyanthus and Primroses are charmingly fresh and bright. Near the north end is what is termed the "Rootery," a great number of roots of Elms and Beeches affording convenient nooks for trailing or shade-loving plants of many kinds.

To give a more detailed review of the rockery and principal plants employed on it, we may commence at the south end, leading from the Cumberland Gate, where the first object of interest is a large *Osmunda regalis*, 5 or 6 feet in diameter, and nearly a ton in weight, round which on a nearly vertical piece of work many of the common British Ferns grow luxuriantly. Dotted here and there are small patches of Squills, the Spring Leucium, and common Daffodils. Some of the stones are very interesting on account of the *Asplenium Ruta muraria* growing in the crevices, which was imported with them from Cheddar, and has taken to its new home readily. On the opposite side is a deep recess occupied with a fine specimen of *Arundinaria falcata*, the side rocks being covered with numerous varieties of British and hardy Ferns. Near by is a large patch of *Primula glaucescens* in fine health, and promising a good show of flowers.

The bog garden and waterfall, of which a view is given in our engraving (fig. 56), is surrounded with vertical walls to the height of 5 or 6 feet, and is the only attempt made at geological formation. At the farthest point from the walk it narrows into a dome, and over a natural-looking projected ledge the water falls into a basin on the bog level, and is carried away by a small stream that winds through it, finally escaping in the surface-water drain. The stream is so constructed as to irrigate the bog to any degree of dampness desired, and at the back of the basin Filmy Ferns have been planted and are now in a fair condition of health, although the position is rather exposed. On a ledge well shaded and under the influence of the saturated atmosphere, *Campanula cenisia* is quite at home, as also is the white variety of *Silene acaulis*; and under an overhanging ledge *Myosotidium nobile*, the New Zealand Forget-me-not, is in perfect health. *Sarracenia purpurea* in the bog is happy; *Orchis foliosa* and the so-called *Juncus zebraus* and *striatus* are fair examples of the size they attain under favourable circumstances and without disturbance. In the niches facing the walk the pretty *Ramondia pyrenaica* has taken firm hold. During last year numerous plants of *Hyacinthus candicans* were handsome on the rock at the side of the waterfall, flowering very strongly, as shown in the photograph.

On a small piece of neat work near this are many varieties, such as *Saxifraga marginata*, *Calceolaria plantaginea*, *Silene Elizabethæ*, *Saponaria lutea*, and *S. cæspitosa*, Edelweiss, and a fine specimen of *Saxifraga longifolia* nearly a foot in diameter. On a plateau or terrace just above this, and having a graceful curve, such plants as *Convolvulus mauritanicus*, *Tropæolum polyphyllum*, speciosum, and tricolorum, *Potentilla tridentata*, and many other plants find a pleasant home, all of which are extremely showy in their season. Further on we come to the home of *Androsace obtusifolia*, *A. lanuginosa*, &c., and a large patch of *Primula floribunda* is very handsome. *Hypericum Burseri*, also rare, and *Primulas Muretiana*, *minima*, *pedemontana*, *Clusiana*, *Wulfeniana*, and some pretty varieties of *P. denticulata* are very interesting. *Kniphofia caulescens* is also very healthy in a protected corner, although the one exposed on the top is dwarfer and more sturdy.

In a bed devoted to seaside plants *Mertensia maritima*, *Silene maritima*, *Plantago maritima*, *Armeria maritima*, *Eryngium maritimum*, *Crithmum maritimum*, and *Convolvulus Soldanella*, are doing well, the project being quite a success. In the "pockets" around this the New Zealand Veronicas, *carnosula*, *pinguicula*, *Haastii*, *elliptica*, *lævis*, *chatamica*, and many others are predominant, and near the top a fine specimen of the large and pretty yellow Rose from Afghanistan, *Rosa acæ*. The hardy Orchids are grown in a recess adjoining another vertical wall, and these planted have established themselves well under a dense carpet of *Veronica repens*. They are planted on terraces formed by a semicircle of roots. One part of the bed is devoted to florists' Primulas, and they are exceedingly pretty, showing some very fine colours. One more remarkable than the others is a hybrid between *P. elatior* and *P. vulgaris* raised by Mr. Christie, and which partakes of the character of the two species. On the wall, which is surrounded by rustic work, *Primula obconica* promises well, as also does *P. verticillata*, *Iberis jucunda*, *Arabis blepharophylla*, the Cheddar Pink,

and *Lychnis alpina*. There is also a specimen of the rare *Oxalis eneaphylla*, as much at home as it would be in the Falkland Islands. The new and rare *Rhododendron afghanicum* is in perfect health. Among the roots, where the taller and coarser plants are grown, patches of *Chionodoxa Lucilæ*, *Cyclamen hederæfolium*, *Primula japonica*, and *P. denticulata* are very pretty on the other side, and going from north end we come to the rare *Daphne Blaygayana* and *D. rupestris*, throwing their sweet-scented flowers out of the crevices. *Doronicum plantaginicum excelsum* is beautifully in flower, and *Iberis saxatilis*, near which is the pretty *Polygala Chamæbuxus rosea*, are quite happy. Recesses are given to Himalayan *Rhododendrons*, and *R. ciliatum* is showing its pretty rosy-tinted flowers in profusion without the slightest protection.

Peat and shade-loving plants are well attended to, a large bed being entirely devoted to them. It is surrounded by large roots, close under which are nestling such plants as *Arum pictum*, *Arisarum orientale*, and others. *Dentaria bulbifera* and *digitata*, *Clintonia Andrewsii*, and *Spigelia marilandica* being particularly noticeable. *Lilium giganteum*, *L. cordifolium*, *auratum*, and a few others are also planted here. A fine plant of *Helonias bullata* is showing flower. *Trilliums grandiflorum*, *sessile*, *foetidum*, &c., along with a rare species of *Swertia*, *S. multicaulis*

partment, Mr. D. Dewar, the whole of it being completed and opened to the public in about three months from its commencement.

BRISTOL SPRING SHOW.

MARCH 19TH AND 20TH.

THE fourteenth annual Exhibition of spring flowers arranged by the well-known Clifton Horticultural Society, and held in the Victoria Rooms, Clifton, was generally admitted to be the best in every respect yet held. Classes were provided for all kinds of flowering plants in season, as well as for fine-foliage plants, cut flowers, and fruit, in nearly all of which the competition was close and good. The Committee of gardeners under the direction of the active Hon. Secretary, Mr. G. Webley, arranged the Exhibition in their usual excellent style, and to the evident satisfaction of all who visited it.

Hyacinths were the principal feature of the Show, and of these there were immense numbers shown, the majority of which were highly creditable to the growers. Tulips, Narcissus, and Crocuses were also well represented. The principal prizes for bulbs were given by the Treasurer, W. Derham, Esq., and were respectively of the value of three, two, and one guinea.

FIG. 56.—THE KEW ROCKERY.

from the Himalayas, *Cypripedium pubescens*, *arietinum*, *macranthum*, and *japonicum* are quite at home. Near here *Mitchella repens* and a collection of *Pyrolas* are also doing well, *Rhodostachys Andina*, and a fine clump of *Pulmonaria saccharata*. In the front is a charming *Lychnis Lagasæ* nestling on a ledge, is healthy and showing plenty of flower. *Morina Coulteriana* and strong plants of the pretty *Verbascum olympicum* are fine. A large patch of *Saxifraga valdensis* on a sloping bank looks beautiful, as also does the rare *Gilia Brandegii* and *Androsace sarmentosa*. In a bed on which the low-growing *Salixes* are grown bulbs of *Muscari* have been planted, and now they are flowering freely. A large plant of *Aciphylla squarrosa*, healthy, and in a small bed at the cool end a large clump of *Gentiana lutea*, together with *Olivieri*, *septemfida*, and the variety *cordifolia*, with *Frœlichii*, *plogifolia*, *decumbens*, *acaulis alba*, *verna*, *affinis*, *Kaufmanniana*, *Walujewi*, *Fetisowii*, *calycosa*, *umbellata*, *macrocalyx*, and *asclepiadea alba*. At the end, and next the Ferns a large bed is divided into four or five divisions, in which are grown *Lonicera borealis*, *Rubus chamæmorus*, *Campanula pulla*, &c.

It only remains to add that the general plan was designed by Professor Dyer, who superintended the construction, his ideas being satisfactorily carried into execution by the foreman of the herbaceous de-

the collection to consist of eighteen Hyacinths, distinct, and twelve pots of Tulips. Mr. J. Marsh, gardener to M. Dunlop, Esq., took the first prize with even and excellent examples. Hyacinths King of the Blues, L'Or d'Australie, C. Dickens, Princess Mary of Cambridge, Lord Derby, Mont Blanc, Haydn, Fabiola, Pineman, Paix de l'Europe, L'Innocence, Gigantea, Grandeur à Merveille, Gigantea, French Khan, General Pelliser, and Lord Macaulay. Of the Tulips the best were Vermillon Brilliant, Murillo, Vuurbaak, Proserpine, Yellow Prince, Kaiser Kroon, Joost Van Vondel, White Pottebakker, Tournesol, Imperator Rubrorum, and Rex Rubrorum. Mr. H. K. Ward was a very close second, his group including many of the above-named varieties, and in addition extra fine specimens of Hyacinths Baroness Von Tuyl, Blondin, and Czar Peter. The third prize was awarded to Mr. A. Hancock, gardener to A. W. Summers, Esq., this exhibitor having a creditable collection, among which were several good new sorts. Mr. G. Webley took the lead in a very large class devoted to twelve Hyacinths, distinct, his most noteworthy spikes being of Pineman, L'Innocence, Lord Derby, General Havelock, King of the Blues, Admiral de Coligny, and Grand Lilas. Mr. W. Fox, gardener to Mrs. Hurle, had among others excellent examples of Von Schiller, Mont Blanc, and General Havelock, and took the second prize; the remaining prize going to Mrs. Gilbert Howes, and there were seven other good collections staged. In the open class for twelve Hyacinths in six distinct varieties Mr. J. Cypher took the lead with perfect examples of

L'Innocence, Anna, Von Schiller, Czar Peter, General Havelock, and Vieur Cook. To these was also awarded the silver medal of the Royal Horticultural Society offered for the best twelve Hyacinths in the Show. Mr. W. Dobson was a good second in this class. The Messrs. Garaway offered special prizes for twelve Hyacinths in four distinct colours, and Mr. Webley was again in the first position, the second prize being won by Mr. C. Taggett, who was followed by Mr. W. Fox, and there were several other good collections staged. Mr. G. Milliner, gardener to Miss Richardson, had the best six Hyacinths, distinct, the remaining prizes going to Messrs. Fox and S. P. Budd in the order named.

The best four pots of single Tulips, as well as double varieties, were staged by Mr. C. Taggett, who had fresh examples of well-known varieties; and Messrs. Webley, Mr. O'Brien, gardener to R. B. King, Esq., H. K. Ward, and G. Milliner were the other prizewinners in the two well-filled classes. Mr. Taggett had also the best four pots of the attractive Tulip Vermillon Brilliant, of which there were a great number staged. Mr. W. Fox staged the best six pots of Polyanthus Narcissus, and was followed by Messrs. G. Howe, gardener to L. Fry, Esq., M.P., and Mr. O'Brien, all having capital examples of such sorts as Grande Monarque, Queen Victoria, Groot Voorst, Double Roman, Soleil d'Or, and Gloriosa. Crocuses were shown better than usual, the prizewinners being Messrs. W. H. Lintern, gardener to W. Butler, Esq., W. Dobson, and C. Taggett.

Probably the greatest attraction were the three beautiful groups of miscellaneous plants, arranged on a space 12 feet by 7 feet, the first prize for which was a silver cup. The greater portion of the plants employed were in flower, among these being many Orchids. Mr. F. Perry, gardener to H. Cruger Miles, Esq., won the cup with a formal closely packed group, in which were several well-flowered examples of *Dendrobium nobile*, *D. fimbriatum oculatum*, *Oncidium cuculatum*, *Odontoglossum Inscayii*, *Laelia harpophylla*, *Odontoglossum Andersoni* with two fine spikes, *Cattleya Trianae*, and *Cypripedium barbatum grandiflorum*, fine. Besides these there were many well-flowered Azaleas, Ericas, Anthuriums, Acacias, Roses, Amaryllises, and Deutzias. Mr. W. Rye, gardener to J. Derham, Esq., was a close second, his group being also very formal and gay. Included were well-flowered specimens of *Imantophyllum miniatum*, *Pimelea spectabilis*, *Erica Cavendishiana*, Azaleas, Lachenalias, and a few Orchids, of which the best was the beautiful and distinct *Cypripedium barbatum Crossianum*. The third-prize group, arranged by Messrs. W. Maule & Son, was in a very different style from the others, and was, in fact, too free and open for the materials at command. Orchids largely predominated, and of these the most conspicuous were *Dendrobium Wardianum*, *D. macrophyllum*, *D. Parishii*, *D. Pierardii*, *D. thyrsoiflorum*, *D. chrysotoxum*, *Lycaste Skinnerii*, *Celogyne cristata*, *Angraecum citratum*, *Vanda tricolor*, and *Cymbidium eburneum*.

Mr. Rye staged the best six fine-foliaged plants, and in addition to the money prize secured a Banksian silver medal of the Royal Horticultural Society. The group consisted of fine healthy specimens of *Crotona Weismannii* and *interruptus*, *Dracaena Draco*, *Latania borbonica*, *Areca sapida*, and *Pandanus Veitchii*. The second prize was awarded to Mr. J. H. Stevens, gardener to S. Budgett, Esq., and the third to Mr. Hancock, the specimens in each case being large and healthy. Mr. Stevens took the lead with four specimens, and was followed by Messrs. H. K. Ward and W. Rye, all staging creditable specimens. The best four stove or greenhouse flowering plants were staged by Mr. F. Perry, these consisting of fresh well-flowered specimens of *Azalea Roi Leopold*, *Erica elegans*, *Genetyllis tulipifera*, and a *Pimelea*. In Mr. Hancock's second-prize collection was a beautifully flowered specimen of *Rhododendron Princess Royal*; Mr. Rye took the remaining prize. For a single specimen Mr. H. Stevens was first with *Rhododendron Gibsoni* in good condition, and was followed by Mr. W. Bannister, gardener to H. St. Vincent Ames, Esq., who had a fine plant of *Chorozema illicifolium*, Mr. Hancock being third with a good *Franciscea confertiflora*. A considerable number of well-flowered trained Azaleas were shown, the best four specimens, consisting of Mrs. Turner, Model, Dr. Jereniker, and Iveryana, were staged by Mr. F. Edwards, gardener to J. Lysaght, Esq. Other successful exhibitors in the different Azalea classes were Messrs. C. Taggett, Hancock, W. Fox, G. Howe, F. Perry, H. Stevens, H. Spry, gardener to Mrs. G. F. Prideaux, and W. Rye. Mr. G. Howe had the best four *Rhododendrons*, and Messrs. Maule & Son were first with a group of forced hardy plants, both classes being poor, and contained many of the worst exhibits in the Show. Amaryllis were well shown by Messrs. G. Howe, M. O'Brien, and W. Fox, who took the prizes in the order named. Table plants were well shown by Messrs. H. Stevens, H. Spry, and G. H. Shelton, gardener to H. K. Wait, Esq., and small Ferns by Messrs. Stevens, J. Loosemore, gardener to W. Cooper, Esq., and J. Marshall, gardener to M. Whitwill, Esq., and took the prizes in the order named in each instance. Mr. Rye had the best group of specimen Ferns, the second prize in a good class going to Mr. H. Bannister. Primulas were well shown by Messrs. Stevens, W. Bannister, and J. Marshall. Cinerarias by Messrs. F. Edwards, G. Milliner, and F. Perry. Mignonette by Messrs. G. Howe, F. Edwards, and H. Spry. Lily of the Valley by G. Howe and G. W. Shelton. Cyclamens by Messrs. S. Blacker, gardener to Miss Charles; G. Howe, Messrs. Maule. Tricolor Pelargoniums by Messrs. C. Taggett and G. Milliner; and Violets by E. S. Cole and H. Stevens, the prizes being awarded in the order named in each instance.

Mr. W. H. Mould had the best stand of cut Roses, among these being good blooms of *Maréchal Niel*, *Niphetos*, *M. Bosanquet*, *Goubalt*, and *Souvenir d'un Ami*. Mr. S. Blacker was a good second, his best blooms being of *Duke of Edinburgh* and *Madame Berard*. The hand bouquets and vases were very good as usual, but the ladies' decisions were rather inconsistent, especially in the classes for the former. Mr. E. S. Cole was awarded the first prize for a lightly arranged bouquet of medium-size, in which Orchids and Roses were principally employed, the second prize going to Mr. J. Cypher, Cheltenham, for a very fine and perfectly arranged bouquet, in which *Phalaenopsis*, *Cattleyas*, *Odontoglossums*, *Maréchal Niel* Roses, and Lily of the Valley were conspicuous. Mr. W. H. Mould took the remaining prize. Messrs. H. Stevens, H. K. Ward, and J. Loosemore were the successful exhibitors of a bouquet from which Orchids were excluded, but all appeared to have too many choice flowers at their disposal. Messrs. E. T. Hill, E. S. Cole, and M. Hookings had the best vases of cut flowers, and all were light and elegant.

Grapes were not well shown, but the few Pears and Apples in competition were of good quality. A good dish of *Beurré Rance* gained Mr. R. H.

Taylor the first prize for Pears, Mr. J. Marshall following with a good dish of *Easter Beurré*. Mr. G. Milliner had a fine dish of *Blenheim Pippin* Apples, and took the first prize, Mr. Bannister following with *Cox's Orange Pippin*, sound and good in quality, Mr. J. Marshall being third with a good dish of *Scarlet Nonpareil*. Mr. J. Pullin was the only exhibitor of Cucumbers, and was awarded the first prize for a remarkably fine brace of *Telegraph*. Several very fine Mushrooms, and which were grown in a Potato frame, were shown by Mr. Aplin, gardener to W. M. Baker, Esq., Hasfield Court, Gloucester, and were highly commended. From Mr. Vallance, gardener to Dorien Smith, Esq., Scilly Isles, came a charming group of cut *Narcissus* in great variety, and Mr. Bloodworth had a fine group of *Roses* and other plants not for competition. Messrs. Garaway & Co., Durdham Down Nurseries, staged upwards of 200 Hyacinths, all being highly creditable to this well-known Bristol firm. Such varieties as *Princess Mary* of Cambridge, *Lord Byron*, *Haydn*, *Lord Derby*, *President Lincoln*, *Cavaignac*, *Marchioness of Lorne*, *L'Innocence*, and *Vuurbaak* were among the best shown by them, and the group added materially to the general effect.

ROYAL METEOROLOGICAL SOCIETY.

THE usual monthly meeting of this Society was held on Wednesday evening, the 19th inst., at the Institution of Civil Engineers, Mr. R. H. Scott, F.R.S., President, in the chair. Messrs. W. Bailey, M.A., W. L. Boire, A. L. Ford, N. Leopold, A. F. Lindemann, F.R.A.S., and Rev. E. B. Smith were elected Fellows of the Society.

The President read a paper entitled, "Brief Notes on the History of Thermometers." He stated that the subject had been handled in a comprehensive manner by Mons. Renou a few years ago in the *Annuaire* of the French Meteorological Society, so that he should merely mention some of the leading points. The name of the actual inventor of the instrument is unknown. The earliest mention of it, as an instrument then fifty years old, was in a work by Dr. R. Fludd, published in 1638. Bacon, who died in 1636, also mentions it. The earliest thermometers were really sympiezometers, as the end of the tube was open and plunged into water, which rose or fell in the tube as the air in the bulb was expanded or contracted. Such instruments were, of course, affected by pressure as well as temperature, as Pascal soon discovered. However, simultaneously with such instruments, thermometers with closed tubes had been made at Florence, and some of these old instruments were shown at the Loan Collection of Scientific Apparatus at South Kensington in 1876. They are in the collection of the Florentine Academy, and in general principle of construction they are identical with modern thermometers. Passing on to the instrument as we now have it, Mr. Scott said that most of the improvements in construction in the earliest days of the instrument were due to Englishmen. Robert Hooke suggested the use of the freezing point, Halley the use of the boiling point, and the employment of mercury instead of spirit, and Newton was the first to mention blood heat. Fahrenheit was a German by birth, but was a protégé of James I., and died in England. Réaumur's thermometer in its final form owes its origin to De Luc, while the centigrade thermometer, almost universally attributed to Celsius, was really invented by Linnæus. Celsius's instrument had its scale the reverse way, the boiling point being 0° and the freezing point 100°. Mr. Scott then gave a brief account of some of the principal forms of self-registering and self-recording thermometers.

After the reading of this paper the meeting was adjourned, in order to afford the Fellows and their friends an opportunity of inspecting the exhibition of thermometers and of instruments recently invented. This exhibition was a most interesting one, and embraced 136 exhibits. The thermometers were classified as follows:—1, Standard; 2, Maximum; 3, Minimum; 4, Combined Maximum and Minimum; 5, Metallic; 6, Self-Recording; 7, Solar Radiation; 8, Sea; 9, Earth and Well; 10, Thermometers used for special purposes; 11, Thermometers with various forms of bulbs, scales, &c.; and 12, Miscellaneous Thermometers. In addition to these, there were also exhibited various patterns of thermometer screens, as well as several new meteorological instruments, together with drawings, photographs, &c.

NARCISSUS PALLIDUS PRÆCOX.

THE great value of this Daffodil consists in its flowering extremely early in the year, and this season Mr. Barr has had flowers in his nursery at Tooting from the first week in January. On February 12th Mr. Barr exhibited a number of flowers at South Kensington, which were greatly admired, and a first-class certificate was readily granted for the variety. The colour is a delicate pale clear yellow, the crown being slightly darker than the petals, 1½ inch deep, with a slightly recurved and irregularly cut margin, the petals being nearly white, elliptical in form and spreading regularly. It is very free, and grows in any ordinary garden soil that is not excessively wet or heavy.

N. pseudo-Narcissus var. *moschatus* is somewhat of the same type, but is much later in flowering, and easily recognised on comparison with *N. pallidus præcox*. It is somewhat curious that both the names adopted for this variety are synonyms of other and quite distinct sorts. Thus *N. pallidus* is a synonym of *M. dubius*, while *Helena præcox* was the title given by Tenore to the plant now known as *N. tazetta* var. *italicus*.

GLADIOLI DISEASE.—Kindly permit me to say, while agreeing generally with what "D., Deal," urges in your last issue, I am particularly inclined to concur that "climate" has much to do with success. But instead of "climate," which we cannot control, I would use the word "aspect," and that is to a great extent the secret—if I may so call it—of whatever success I have had in *Gladiolus* culture. The borders I grow them in are wholly closed against the north winds, and slope to the

south at a very steep angle, thereby securing every ray of sunshine. It is curious that the most successful amateur gentleman grower and exhibitor in Ireland, J. F. Lombard, Esq., Rathmines, Dublin, Mr. F. W. Burbidge tells me, has a garden sloping to the south in the same way. The heat I once experienced going to Fontainebleau I admit we never have in Ireland, but by planting early my Gladioli mature before December. —W. J. MURPHY.

ROYAL HORTICULTURAL SOCIETY.

MARCH 25TH.

THE second Promenade Show of the season was exceedingly well attended by exhibitors and Fellows, and during the afternoon quite a large company assembled. The conservatory was filled with exhibits, the groups of Hyacinths forming the chief feature, though the miscellaneous contributions were both numerous and interesting.

FRUIT COMMITTEE.—John E. Lane, Esq., in the chair. Present, Messrs. J. Roberts, J. Willard, J. C. Mundell, W. Denning, S. Lyon, C. Silverlock

Fig. 57.—*Narcissus pallidus præcox*.

Harry J. Veitch, G. Bunyard, and Phillip Crowley. The principal exhibit before this Committee was a collection of Rhubarb from Chiswick, in which a number of varieties were represented. Under Early Red or Albert were classed Mitchell's Royal Albert, Crimson Perfection, and Scotch Mammoth, which were found to be identical with the type. Under Linnæus were arranged Lawson's Victoria, Buckley's Crimson, Salt's New Emperor, and Burr's Goliath. Other distinct sorts were Buck's Early Red, which produces a small stem but of excellent colour; Dancer's Early Red is somewhat similar but larger. Hawkes' Champagne was considered the best of all, being early, producing a fine stem, and of rich colour. A first-class certificate was awarded for this. Baldrey's Scarlet Defiance and Carter's Crimson Perfection were found to be identical, while Victoria and Stott's Monarch were considered to be distinct late and meritorious varieties.

Mr. R. Gilbert, Burghley Gardens, Stamford, was awarded a first-class certificate for his *Universal Savoy*, which has been previously referred to. Cooked specimens were tested by the Committee, and the opinion was greatly in its favour. In some stages it appears much like a Cabbage, but the outer leaves preserve the bullated appearance of the Savoy. Mr. Yull, Dereham, Norfolk, sent samples of dwarf white Broccoli with good white heads. Specimens of the Purple Sprouting Broccoli were sent from Chiswick, and a vote of thanks was accorded to Mr. T. Oldham, The Gardens, Friern Walch, North Finchley, for a collection of eighteen dishes of well-kept Apples.

FLORAL COMMITTEE.—Section A.—Thomas Moore, Esq., in the chair. Present, the Rev. G. Henslow and Messrs. John Fraser, H. Herbst, James Hudson, H. Ebbage, H. Williams, H. Ballantine, J. Dominy, James O'Brien, E. Hill, John Woodbridge, and F. R. Kinghorn. Section B.—Shirley Hibberd, Esq., in the chair. Present, W. Bealby, J. James, J. Child, G. F. Wilson, D. Lathbury, and W. B. Kellock. Mr. Heims, gardener to F. A. Philbrick, Esq., Q.C., Oldfield, Bickley, sent a fine spike of *Odontoglossum Jenningsianum* with fourteen flowers; a plant of *O. triumphans* var. *punctatum*, a distinct variety, with the petals finely dotted with rich brown. *Eriopsis rutidobulbus* with a spike of curious brownish flowers and a white-tipped lip was also shown, together with a *Cypripedium* named *syhetense*, somewhat like a small *C. insigne*. W. Lee, Esq., Downside, Leatherhead, exhibited several Orchids, amongst which were *Masdevallia Schlimi*, *Masdevallia*

Chelsoni, *Leptotes bicolor* flowering very freely, and two others, for which certificates were awarded. Mr. J. Walker, Thame, Oxon, was awarded a vote of thanks for two boxes of Roses, including some fine blooms of Thomas Mills, Senateur Vaisse, Helen Paul, Cheshunt Hybrid, Climbing Devonensis, and Maréchal Niel. Mr. C. Turner, Slough, sent three Tree Carnations; one Ruby, a distinct shade of violet purple, very full; Rufus, bright scarlet, large and of good form; Mrs. Llewelyn, bright clear pink, very full broad petals. The Rev. E. H. Kittoe, Boldmere Vicarage, New Oscott, Birmingham, sent a plant of *Agathosma rugosa*, a plant allied to the *Diosmas*, with small heads of white flowers very powerfully fragrant.

J. H. Mangles, Esq., Valewood, Haslemere, exhibited five magnificent trusses of *Rhododendron grande*, bearing over two dozen flowers, each of large bell-like white flowers. These superb specimens were greatly admired and were awarded a vote of thanks. Mr. J. Burnett, The Gardens, Deepdene, Dorking, showed a collection of *Rhododendron* flowers from plants out of doors, several handsome varieties of the *R. Nobleum* type being remarkable for their great size. Mr. Wilson, gardener to H. M. Pollett, Esq., Fernside, Bickley, sent several spikes of *Odontoglossum elegans*, and a plant of a fine variety of *Odontoglossum Ruckerianum* well coloured. A vote of thanks was accorded. Major Lendy, Sunbury House, Sunbury, showed a plant of *Cirrhopetalum picturatum* with four spikes of its curious brownish flowers, for which a cultural commendation was awarded. Mr. Harding, The Gardens, Orton Hall, Peterborough, was accorded a vote of thanks for a box of fine Maréchal Niel Roses. W. Soper, Esq., 307, Clapham Road, was also accorded a vote of thanks for a healthy plant of *Cattleya Loddigcsi*, with eleven of its distinct mauve-purple flowers.

Mr. J. Graham, Cranford, Middlesex, exhibited a box of a rich crimson Polyanthus named Sir Gerald Graham, which had been flowering in the open ground from October. Plants of the large single yellow Wallflower Cranford Beauty, which was so much admired last year. A vote of thanks was accorded. A vote of thanks was awarded to Mr. Bain, gardener to Sir Trevor Lawrence, Bart., M.P., Burford Lodge, Dorking, for a group of Begonias flowering most profusely. The principal varieties were odorata with white flowers, Nitida with pale pink flowers, and Roetzli, rich coral red. A fine pot of *Freesia refracta alba* was also sent. Mr. Frank Miles, 26, Tite Street, Chelsea, sent a flower of a Tulip from north-west Persia, found by Mr. E. O'Donovan in his journey to Merv. It was bright scarlet with black spots at the base of the petals, somewhat like a species of *Papaver*. Mr. T. P. Bethell, 24, Cable Street, Liverpool, exhibited a number of the "Unique" boxes for sending flowers by post.

First-class certificates were awarded for the following:—

Amaryllis Col. Burnaby (Veitch).—Flowers of great size and substance, 7 inches in diameter, with proportionately broad petals, brilliant, almost dazzling scarlet, two flowers in a head, and two spikes to the bulb. This is one of the most imposing of the many grand Chelsea novelties.

Amaryllis Mrs. Shirley Hibberd (Veitch).—A beautiful variety with flowers 6 to 7 inches in diameter, deep crimson, with a pale green centre and white tips. The plant had two spikes and two flowers each.

Amaryllis Sir Redvers Buller (Veitch).—A superb variety; flowers four in a head and 7½ inches across, the petals 3 inches across; rich scarlet with a broad central white stripe.

Hyacinth General Gordon (Veitch).—A fine variety. Spike very large, but rather loose. The floral portion 8 inches deep; flowers deep purplish blue, single, with narrow petals.

Hyacinth Harlequin (Veitch).—A single variety with a very compact spike; flowers mauve-purple, white in the centre, and very distinct in colour.

The four following new Hyacinths are worthy of especial note, though they were not certificated:—

General Graham.—Single, dark rich shining blue, very compact dense spike. Considered by many superior to General Gordon.

Minerva.—Double, of a peculiar salmon tint, compact spike.

Lord Derby Improved.—A variety with wonderfully large bells and spikes.

Lady of the Lake.—Single, pale primrose yellow, close spike.

Laelia calistoglossa (Mr. Ballantyne, gardener to Baron Schröder, The Dell, Egham).—A magnificent species with narrow twisted mauve sepals and petals, the lip 2½ inches across, of the richest crimson, the margin slightly undulated. The flowers are 7 to 8 inches in diameter.

Odontoglossum Oerstedti (W. Lee, Esq.).—A pretty dwarf species with small white flowers, the lip stained with yellow at the base. The pseudobulbs are about 1 inch in diameter, and the leaves 2 to 4 inches long. The plants were in small pans and had twelve to eighteen flowers each.

Cattleya Trianae var. *Leeana* (W. Lee, Esq.).—A magnificent variety, with flowers 7 inches in diameter; the petals 3 inches broad, pale mauve purple; the lip 4 inches long, intensely rich crimson. The plant shown, which is an extremely valuable one, was growing upon a block, and had four grand flowers.

Odontoglossum macrospilum (Williams).—A magnificent Orchid, somewhat of the *Alexandrae* type; the flowers 3 inches in diameter, sepals and petals white heavily blotched with chocolate, the lip being triangular in form, serrated at the margin, yellow at the base, and with heavy chocolate spots.

Rose Anne-Marie de Montravel (Bennett).—One of the Polyantha varieties, with small but neat double pure white flowers, produced in great abundance. They were shown in 6 and 7-inch pots, and were very attractive.

Auricula Hetty Dean (Dean).—A yellow self variety with neatly formed flowers, the paste well defined, and the body colour a clear shade of yellow.

Wallflower Bedfont Yellow (Dean).—Very dwarf, with dark green sturdy leaves; the flowers 1½ inch in diameter, pure yellow, in a dense compact truss.

Adiantum rhodophyllum (Veitch).—A distinct and beautiful Fern with bipinnate fronds; the pinnules 1 inch across, irregularly semicircular in form; the young fronds being of a reddish tint like *A. rubellum*. Dwarf and compact in habit.

SCIENTIFIC COMMITTEE.—Sir J. D. Hooker in the chair.

Black Knot in Birch.—With reference to this subject, brought before the Committee at the last meeting, Mr. MacLachlan observed that Prof. Trail had come to the same state of uncertainty as to *Phytophthora* being the cause of it as himself, inasmuch as by his experiments he obtained a small gall-like structure, which would, however, develop no further, and failed to produce the characteristic features of the disease.

Experiments in Protecting Potatoes from the Disease.—A sub-Committee was nominated to superintend the experiments to be carried out at Chiswick, consisting of Sir J. D. Hooker, Messrs. Plowright, W. G. Smith, G. Murray, S. Hibberd, Dr. Masters, Mr. MacLachlan, Mr. Bower, and Rev. G. Henslow.

Apples Attacked by Fungi.—Mr. MacLachlan exhibited Apples showing cup-like depressions. They were referred to Mr. Murray for examination.

Rhododendron Wightii.—Mr. Mangles exhibited a truss of this species, and traced the history of its occurrence and descriptions as follows:—*Gardeners' Chronicle*, 1856, p. 213, "R. Wightii bloomed at Standish's, not equal to the description by Hooker in 'Himalayan Rhododendrons'; it turned white when open, of a good shape, was 3 inches across, and petals singularly transparent. Hooker figured it as yellow with red spots. In the Kew Herbarium is a sheet of R. Wightii, signed 'J. D. H. Lachen, 12,000 feet,' and labelled flowers white." Another ref. was from Combe Royal, where it also blossomed white. Herr Otto Foster, of Austria, writes:—"Years ago I had R. Wightii with flowers." The bud scales showed the same rich chestnut colour as in Hooker's figure.

Primula elatior.—Mr. Boulger showed an extremely dwarfed specimen as grown in a London atmosphere, the corolla being about half an inch across.

Proliferous Cardamine.—Mr. Houston showed a specimen having a bud growing between the petal and pistil.

Flowers for Open Ground.—Mr. G. F. Wilson exhibited several specimens—e.g., a Camellia (planted out in October from a cool house) was in full bloom. Sir J. D. Hooker remarked upon the various degrees of hardness of this plant. *Primula denticulata* with very fine trusses, &c.

Plants Exhibited.—Mr. Loder brought *Scilla italica* var. *alba*, a rare form; *Muscari lutea*, very sweet-scented; *Chionodoxa nana*, &c. Dr. Low brought two species of *Cheiranthus*, *longifolia* and *mutabilis*, which are usually cut by frost, but were not at all injured in the past winter; also a *Richardia* with leaf and undeveloped spadix. A *Cerinthe* major, which for six or seven years had borne yellow flowers, reverted to brown, the normal colour.

"Black Spot" Fungus on Orchids.—Mr. W. G. Smith exhibited leaves belonging to *Vanda* and *Cattleya*, as forwarded by a correspondent of *Garden*, covered with black disease pustules. Mr. Smith said the sporangia, the fungus described under *Protomyces concomitans*, B., were very distinct in the discoloured patches.

Black Fungus Patches on Oranges.—Mr. Smith also exhibited blackened Oranges, the sooty patches being caused by the fungus known as *Capnodium citri*.

"Bunt" Disease of Wheat.—Mr. Smith pointed out the fact that the Rev. M. J. Berkeley in 1847 described and illustrated the secondary spores of germinating Bunt as distinctly septate, like a *Fusisporium*. Since then, and especially after the publication of Tulasne's memoir in 1854, the spores have been invariably described and illustrated as non-septate. Dr. Oscar Brefeld, however, in his recent magnificent work on Smuts and Bunt illustrates a series of these spores as distinctly septate, and precisely agreeing with the original description and illustration published by Mr. Berkeley.

Corn Mildew and Barberry Blight.—Mr. Smith said in reference to this subject that the *Puccinia* of mildew of corn was perennial and hereditary. It was, however, not so easy to prove that the fungus of Barberry Blight was perennial, as the bush, as well as the fungus, was rare. Mr. Plowright was, however, good enough last spring to send a collection of Mahonia berries on to Mr. Smith, many of which were invaded by *Æcidium berberidis*, Pers. Mr. Smith planted three series of these berries, giving each series three months for germination. Not a single berry germinated or appeared above the ground. Twelve berries, each invaded by *Æcidium*, were also sent on to Mr. B. S. Williams, of Holloway, who planted them under favourable conditions as a test experiment, and not one seed came up in Mr. Williams's pots. Mr. Smith has since sent a series to Chiswick, where Mr. Barron is trying them. Mr. Smith thought the Barberry blight disease, like the mildew of corn, was probably perennial; if so, all the deductions made from experiments with plants saturated with hereditary disease should be received with very great caution.

LECTURE.—The Rev. George Henslow took the *Narcissus* as the subject of his lecture, which was illustrated by many specimens from Mr. Barr's beautiful collection.

With reference to the origin of the name, he explained how in Greek mythology the son of Cephissus and Liriope, slighting the nymph Echo, fell so desperately in love with his own shadow in the stream instead, that death alone could release him from the anguish of such unrequited love. The Naiads mourned for him, and on searching for his body discovered nothing but a beautiful flower instead, which henceforth bore his name.

Coming to more prosaic matters, the genus, though abounding in "forms," is, according to Mr. G. Baker, a limited one. That botanist groups them under three heads—viz., those with long trumpet-shaped crowns or coronas, as the *Daffodil*; those with crowns of a medium length, as in the *incomparabilis* group; and those with a mere rim, as the *Poet's Narcissus*.

Describing the structure of the flower, he pointed out the difference between the family *Amaryllidaceæ*, to which this genus belongs, and that of *Lilies*, which it resembles, the former being known by all its members having the ovary inferior, or below the perianth.

The crown he explained as being a mere outgrowth from the perianth, and would seem to correspond to the rim seen in the corollas of the *Primrose* and *Forget-me-not*. It is not at all characteristic of the majority of the genera in the family, the *Amaryllis* and *Snowdrop*, for example, being entirely without it.

Double flowers are frequent, and are of different kinds:—1, The corona may be filled with a mass of petals, this being derived from weaker bulbs. 2, The perianth and corona may be broken up and repeated many times, so as to form an irregular mass of petals, such arising from stronger bulbs. 3, The petals may be piled up in front of each other, as in a *Rose*. This occurs in the var. *Eystettensis*, first figured by Lobelius in 1581.

With reference to the physiological properties, the *Narcissus* is more or less poisonous, the *Daffodil* and the *Poet's* being especially so, and have been used in medicine as emetics. Other members of the family are poisonous, as *Brunsvigia toxicaria*, which is used by the natives of South Africa to poison fish. It was this which accidentally poisoned Dr. Pattison, though he fortunately recovered.

The *Narcissus* has been long cultivated in England. Gerard, in his "Herball," A.D. 1597, described seventeen kinds; and Parkinson, in his "Paradisus" (1629) figures many and describes ninety-two kinds.

Selecting a few for illustration, Mr. Henslow first alluded to the "Hoop Petticoat," *N. Bulbocodium*, from the W. Mediterranean regions, and which is remarkable for the shape of the crown and the declinate stamens. It is recorded that a bulb of this species having been in an herbarium for twenty years, subsequently revived, was planted and flowered. The *Daffodil*, or *N. pseudo-Narcissus*, is probably the only native species of Great Britain, though *N. poeticus*, &c., are naturalised. It is very variable, especially under cultivation. The size of the flowers quite justifies the terms *maximus*, *major*, *minor*, *minimus* applied to as many varieties. The colour may be all yellow, or the perianth may be white while the crown alone is yellow (e.g., *bicolor*), or all white (e.g., *cernuus*), such as are the Spanish forms.

Double flowers of the larger sorts are common, though that of the true wild *Daffodil* is not. The great double *Daffodil* first appeared in the garden of Vincent Sion of Flandres in 1620. Of the second group with shorter crowns the most important is the form *incomparabilis*, with its many vars. This is now considered to be a hybrid between the *Poet's Narcissus* and the *Daffodil*, although it occurs wild in France and Spain, for Dean Herbert and others have raised it from such a cross; indeed, he thought that by using the pollen of *N. poeticus* successively for two or three generations the *Daffodil* could be converted into *N. poeticus*. A new form with a pale rosy tint and with a strong scent of Violets was exhibited by Mr. Barr, about the size of the common *Daffodil*, but entirely pale yellow in tint. It is remarkable that the purple rim of the cup of *N. poeticus*, with the golden yellow of the *Daffodil*, give rise to an orange tint in the cup of *imperialis*, just as a purple and chrome yellow when mixed on a palette produce a similar orange.

Another important species is *N. odorus*, the *Campernelle*, of a pure yellow colour, with a six-lobed corona, and is very sweetly scented. This is intermediate between the *Jonquil* and *incomparabilis*. Its native home is S. France, Italy, and Dalmatia.

Of the third or short-crowned section, *N. Tazetta* is perhaps the most variable. The Dutch, even in 1800 cultivated as many as 300 forms. It has apparently the widest geographical range; for if not truly wild there, it is at least very largely cultivated in China. All other species appear to be limited between Great Britain and the Caucasus. It is the common *Polyanthus Narcissus*, as it bears many flowers on the scape.

The typical form has a white perianth and a yellow cup; but varies in colour like the *Daffodil*, and may be double as well. The true *Narcissus* of the ancient poets appears to be *N. poeticus* or *N. biflorus*, especially the former, as it is described by Virgil as "purpureus"—doubtless in allusion to the purple rim to the crown, which colour is wanting in *N. biflorus*. Its double form, resembling *Gardenia florida*, is much cultivated for decorative purposes.

Mr. Henslow also exhibited a dried specimen of the *Hyacinth* as wild in S. Europe, to show the great advance made in 300 years. It is not mentioned by Turner, 1548, though Gerard in 1597 had both single and double kinds. He called attention to two remarkable Orchids, *A. Cirrhopetalum*, in which two sepals were coherent to form a false labellum (see *Bot. Mag.*, 1849, tab. 4422), and *Eriopsis rutidobulbon*, first introduced to Kew, where it flowered in 1868, but has rarely flowered since. It was found in New Grenada "growing on the smooth stem of a Palm fully exposed to the sun." See *Bot. Mag.*, 1849, tab. 4437.

SPRING SHOW.

GROUPS.—The conservatory was most attractively furnished with groups of plants, *Hyacinths* occupying the greater portion of the space, and presenting an array of rich colours that was most imposing. Throughout these were remarkable for their fine quality, and very rarely have so many been shown so equal in merit as on this occasion. *Polyanthuses*, *Daffodils*, and the miscellaneous plants shown for certificates before the Committee rendered the meeting one of unusual beauty.

Mr. B. S. Williams, Upper Holloway, staged the largest group of *Hyacinths* in the Show, which included a very fine selection of varieties, most being represented by plants with substantial evenly developed spikes. Light colours such as cream, pink, yellow, pale blue, and white were largely shown in this collection, but with sufficient dark blues and reds to render the display attractive. Lord Derby was in strong force, and mostly with spikes of considerable size. Grand Blue, King of the Blues, and Madame Van der Hoop were similarly noteworthy.

The following varieties were among the most striking and noteworthy in this collection:—**Single Reds.**—*Solfaterre*, rich orange crimson, with a large spike; *Roi des Belges*, crimson, a magnificent colour, but small truss; *Von Schiller*, well known and very effective; *Lady Palmerston*, splendid truss with large pink bells; and *Vuurbaak*, sparkling crimson with large spike. **Single Blues.**—*Grand Maitre*, light blue with enormous spike and fine bells; *Marie*, fine dark blue; and *General Havelock*, rich purple with a good truss. **Single Whites.**—*Grandeur & Merveille*, bluish, splendid spike; *La Grandesse*, charming pure white with very large bells; *Mont Blanc*. **Single Yellows.**—*Ida*, charming canary yellow with a good spike; *Obelisk*, rich yellow, and *Bird of Paradise*. Amongst the double varieties *Koh-i-noor*, a semi-double pink sort with splendid spikes, was conspicuous, as also were *Garrick* and *Laurens Koster*, double blues.

A group of profusely flowered plants of *Azalea mollis*, yellow, salmon, and rose, contributed to the attraction of the Holloway exhibit, together with some richly coloured *Amaryllis*. A dozen large pots of *Lilies* of the Valley with two or three dozen spikes of large bells each, about the same number of *Narcissuses* and sixty pots of *Tulips*, including such well-known and beautiful varieties as the following:—*Vermillion Brilliant*, scarlet; *Ophir d'Or*, yellow; *Adeline*, rose; *Joost Van Vondel*, crimson; *Fabiola* rose, white-flaked; *White Pottebakker*, white; *Rose Luisante*, rose; *Van der Neer*, purple; *Proserpine*, rose; and *Keizer Kroon*, crimson and white, formed another important portion of this group, while sixty pots of dwarf *Cyclamens* and some large seedling *Imantophyllums* completed a display of great beauty and extent, by far the most imposing in the conservatory, and well deserved the gold medal which was awarded to it.

Messrs. J. Veitch & Sons, Chelsea, contributed a very large and handsome group of well-grown *Hyacinths*, the spikes being distinguished by their great size, compactness, and large well-developed bells. The colours also

were extremely pure bright and fresh, and the different shades being tastefully arranged and in due proportion. Some of the spikes had the flowering portion 8 or 9 inches deep, and closely packed with blooms, the foliage being stout and strong. Some examples of Von Schiller, Nimrod, Garibaldi, Electra, King of the Blues, Czar Peter, General Havelock, Grand Maitre, La Grandesse, and Koh-i-Noor were particularly remarkable for their splendid condition; while scarcely less noteworthy were Princess Helena, Cavaignac, and Etna, single reds; Souvenir de J. H. Veen, Enchantress, Grand Maitre, and De Candolle, single blues; and L'Innocence, Miss Nightingale, and Grandeur à Merveille, single whites. A silver-gilt medal was awarded for this fine group.

Messrs. W. Cutbush & Son, Highgate, were awarded a silver-gilt Banksian medal for a group of 100 Hyacinths, representing a great number of the best varieties, the spikes mostly massive, and the colours bright and clear. The pots were surfaced with moss, and the whole group had a very pleasing appearance. Amongst the collection were included fine examples of the following:—Single reds: Von Schiller, Prince Albert Victor, and Lord Macaulay. Single blues: King of the Blues, Lord Derby, The Sultan, and Czar Peter; and single whites: Lady Derby, Mont Blanc, Grandeur à Merveille, and La Grandesse. About twenty pots of Tulips and Narcissuses were also attractive in this group. Messrs. Collins Bros. & Gabriel, 39, Waterloo Road, staged a bright collection of Daffodils and Anemones, the former including incomparabilis Stella, incomparabilis plenus, jonquillus, and poeticus; while the Anemones were chiefly fulgens and multipetala, both very bright in colour.

Mr. T. S. Ware, Tottenham, had a most interesting group of hardy flowers, principally Daffodils, of which a number of choice and distinct varieties were represented. Very notable were incomparabilis albus expansus, with creamy petals and a gold crown; bicolor Horsfieldi, white petals and a long bright yellow crown; princeps, creamy petals and a clear yellow crown over 2 inches long; bicolor Empress, white petals and fine gold crown; Backhousei, with a broad rich yellow crown; Leeds argenteus, white petals and lemon crown. Some of the Narcissuses were grown in pots, and, being furnished with strong foliage, they were very attractive. Several pans of Primula rosea were exceedingly bright, Grape Hyacinths, Chionodoxas, Scillas, Lachenalias—L. Nelsoni and L. tigrina var. Warei, with neat flowers, bright red at the base, yellow, greenish at the upper part and margined with red. The pure white Zephyranthes Treatiae was also very notable in the collection. A bronze medal was awarded for this collection.

Mr. R. Dean, Ealing, showed a collection of Polyanthus, Primroses, Wallflowers, and miscellaneous hardy plants. Very handsome was a large pan of Aubrietia violacea with dark rich purple flowers of the Hendersoni type. Polyanthus Conjuror, rich maroon with a gold centre; Buttercup, bright clear yellow; General Gordon, warm crimson, gold centre; Bridal Wreath, pure white, orange centre; and Primrose White Queen were all good and beautiful. Myosotis dissitiflora Perfection, a variety with large flowers of good colour; and Dornicum austriacum, which has pure yellow flowers 2 inches in diameter, with very narrow florets but closely set. A bronze Banksian medal was awarded to Mr. A. Waterer, Knap Hill, Woking, for a beautiful collection of Polyanthus similar to that staged at the previous meeting, together with the large specimens of Andromeda japonica then described.

A silver-gilt Banksian medal was awarded to Messrs. Barr & Son, Covent Garden, for an extensive collection of Daffodils and Anemones, Muscaris, and miscellaneous hardy plants. All the best varieties of Narcissus in cultivation were represented—the pseudo-narcissus type, the incomparabilis forms, Leedsi, Barri, together with Tazetta varieties, in all a most complete and interesting group.

ROYAL BOTANIC SOCIETY.

MARCH 26TH.

THE first spring Show of the year was held on Wednesday last in the corridor and conservatory of the Royal Botanic Society's Gardens, Regent's Park, and though some of the classes were less well filled than usual the total display was quite equal to the majority of previous early shows. The widened corridor permitted the erection of a double stage down the centre, which, in addition to the side stage and several tables in the conservatory, was fully occupied with exhibits. The weather was unfavourable, but a number of visitors assembled during the afternoon.

Cyclamens.—These were represented by a number of well-grown plants. For twelve plants (amateurs) Mr. Wiggins, gardener to W. Clay, Esq., Kingston, was first with specimens 1 foot to 18 inches in diameter, and bearing two or three dozen flowers each in fine condition. Mr. J. Hill, gardener to H. Little, Esq., Hillingdon Place, was second with much smaller plants and fewer flowers. In the open class, Mr. H. B. Smith, Ealing Dean, was adjudged the first position for very compact specimens bearing flowers of great size and substance. Mr. Hill and Mr. Wiggins followed in the order named with smaller looser examples.

Deutzias.—In the open class for six plants four good collections were staged, Mr. J. Douglas, gardener to F. Whitbourn, Esq., Great Gearies, Ilford, taking the first position with his handsome cylindrical specimen 5 feet high, and loaded with flowers. Mr. H. Eason, gardener to B. Noakes, Esq., Hope Cottage, Highgate, was second with dwarfed, globular, and less formal specimens, Mr. Hill being third with well-grown untrained plants.

Hyacinths.—A beautiful collection of twelve plants gained Mr. J. Douglas the first prize in the amateurs' class, the spikes being extremely large and the bells well developed. The varieties were Von Schiller, Grandeur à Merveille, Cavaignac, La Grandesse, Koh-i-Noor, Princess Mary of Cambridge, King of the Blues, Lord Derby, and Solfaterre. Mr. H. Eason followed, Mont Blanc and Lord Derby being the two finest in his collection.

In the nurserymen's class Messrs. H. Williams & Son won the first place with handsome plants, the spikes being massive and the colours clear. Messrs. Cutbush & Son and Gregory & Evans were second and third with smaller plants.

Narcissi.—Mr. J. Douglas and Messrs. H. Williams & Son, Fortis Green, Finchley, were first and second respectively with twelve pots of Narcissi, both being good collections; the varieties Bazelman major, Bathurst, Grand Monarque, Newton, and Apollo were the favourites.

Tulips.—Only two collections of Tulips were shown in the amateurs' class for twelve, Mr. Eason securing the premier award with fine plants, the flowers large and richly coloured. Mr. J. Douglas was a very close second, his collection being less even, but dwarfier than the other. In the nurserymen's class Messrs. H. Williams & Son, Gregory & Evans, Sidcup, and Cutbush & Son, were the prizetakers, the first showing some fine flowers.

Amaryllises.—Mr. J. Douglas won chief honours for six Amaryllises, showing the varieties Sultan, Endymion, Empress of India, very showy with two spikes, one having six flowers; Sir J. Cathcart, and seedlings. Mr. Hill and Mr. Butler, gardener to H. A. Gibbs, Esq., St. Dunstan's Lodge, Regent's Park, followed with small flowers of little merit. Azaleas were poorly shown, by far the best being the neat globular specimens from Mr. H. James, Castle Nursery, Lower Norwood, for which the first prize was awarded in the nurserymen's class. Of these the varieties were Purpurea, Apollon, Alice, Elegantissima, Coloris nova, and Madame Charles von Eckhaute. Messrs. Paul & Son, Cheshunt, were the only exhibitors of six Roses in pots, and secured the first prize with handsome examples of Claude Bernard, Catherine Souper, Alba Rosea, Mrs. Laxton, La France, and Souvenir d'Elise. The only collections of hardy plants and Primulas were shown by Mr. J. Douglas, for both of which he gained the first prize. The former included Narcissus bicolor Horsfieldi, Jonquils, Fritillarias, and Pulmonaria virginica. The Primulas included villosa hybrida, villosa nivea, and varieties of amœna.

Miscellaneous.—The collection of plants and groups from nurserymen formed an important feature in the Show; but as they were mostly the same as those at Kensington on the previous day they need not be referred to in detail. Medals were granted to all the following:—Messrs. J. Veitch & Sons, Chelsea, staged a group of magnificent Hyacinths, the spikes being of surprising substance and size. They also showed a large group of novelties; choice Orchids, Amaryllises, and Ferns. Mr. B. S. Williams, Upper Holloway, exhibited a large group of Hyacinths, Tulips, Lilies of the Valley, Narcissuses, and Cyclamens, which formed a brilliant display. The same exhibitor had a group of Azalea mollis varieties, Amaryllises, and Imantophyllums. Messrs. Paul & Son, Cheshunt, contributed an attractive group of Roses in pots, well furnished with fresh vigorous foliage and abundant substantial flowers. The Polyanthus varieties, Mignonette and Parqueritte, being very beautiful. Messrs. Wm. Cutbush & Son, Highgate, staged a handsome group of Hyacinths, Tulips, and Narcissuses, the spikes of the first named being of great size and substance. Mr. F. Hill showed a group of richly coloured Cyclamens, the flowers mostly small, but very numerous.

Messrs. Barr & Son, Covent Garden, exhibited a most extensive and beautiful collection of Daffodils, including some scores of distinct varieties of the different sections, while in striking contrast to them were some masses of Anemone fulgens. Mr. T. S. Ware, Tottenham, contributed a choice collection of Daffodils and miscellaneous hardy flowers. Messrs. Collins & Gabriel, 39, Waterloo Road, had a group of Anemones, Narcissuses, and various hardy flowers. Mr. Anthony Waterer, Knap Hill, had a group of Polyanthus and Andromeda japonica. Messrs. Carter & Co., High Holborn, showed a large number of flowers of their Empress Poppy Anemones, representing brilliant shades of red, crimson, blue, purple, and white, Anemone fulgens being well represented. A pretty collection of Auriculas was staged by Mr. J. Douglas, comprising strong plants with large trusses of clean even flowers.

Messrs. Gregory & Evans exhibited a very fine collection of well-grown Hyacinths, together with about twelve pots each of Erica Cavendishii and Erica ventricosa coccinea minor. These were neat dwarf plants well covered with bloom. Mr. James, Woodside, Farnham Royal, staged a magnificent group of Cinerarias, the plants being large and healthy and covered with flowers of immense size. Mr. James' Cinerarias are well known to be almost unequalled, and these were indeed superb. Mr. Wiggins, gardener to W. Clay, Esq., Kingston, also showed a collection of Cinerarias and Cyclamens, both being very large and of good colour.

Mr. A. B. Smith exhibited a very large and very fine collection of Cyclamens, the flowers being of great size and the colours remarkably pure and bright. Mr. H. Eason, gardener to B. Noakes, Esq., Highgate, staged a small miscellaneous collection of plants, consisting of about a dozen pots each of Hyacinths, Tulips, and Lachenalia luteola. This small group looked bright and neat. Mr. John Odell, Willow Vale Nursery, Shepherd's Bush, showed a collection of scarlet Primulas and white Cyclamens; the former though small were of good colour, while the latter were both large and pure.

KITCHEN GARDEN.

MARCH is a busy month in the kitchen garden, as the "dust" which is expected to predominate then is in favour of sowing and planting; but the present March will not be noted for this, as we have had much rain. On this account many seeds which would have been under the soil are still in the bags, and nothing will be lost by this, as it is very much better to sow late than to put them into a cold, wet, unfavourable soil. Good weather, however, may soon be expected, and the most must be

made of it. When work cannot be done on the soil, forward it as much as possible elsewhere, and when good days do occur get all hands to the vegetable quarters. This is the only way progress can be made in changeable weather.

Herbs.—These should now have attention. They are important in all kitchens, and gardeners should be well stocked with them. Mint delights in a rich soil; but when the roots have been planted they need not be disturbed again for many years; but an annual top-dressing of short manure should be put all over the surface every spring. This should be done before growth is much advanced. Sage and Thyme are easily propagated from seed, which should be sown now in good soil. Sage may also be increased from cuttings, and large plants of Thyme may be divided and planted anew. As young healthy well-furnished plants of both may be secured in these ways, old specimens should never be allowed to remain. Sweet Basil must be raised from seed sown under glass; then plant in a frame and grow in this way. Bush Basil is hardier and may be raised in the open, and so may Borage, Burnet, Dill, Horehound, Fennel, Marjoram, Purslane, Savory, Skirret, and Sorrel, all of which should find a place in every herb border.

Potatoes.—Early ones in frames must have plenty of air admitted to them on all favourable occasions. Dig up those matured and refill frames with young Celery and other plants. Protect any coming through the soil in sheltered corners should frost occur. Varieties of all descriptions may now be planted. We are now putting in Schoolmaster, and other late varieties will follow as soon as possible. Admit plenty of air to seed tubers, as this will harden them and make the shoots, which are now pushing freely from all of them, robust and healthy.

Peas.—Spring-sown Peas now require to be earthed up and staked. It is an advantage to keep them always upright. When neglected and allowed to fall over through not being staked in time they never do so well afterwards. Varieties such as Telegraph, Telephone, Giant Marrow, Stratagem, Pride of the Market, and Webb's Electric Light should be sown now to fruit in July. Open the drills wide, put plenty of manure in, sow good seed thinly, and the growths will certainly be robust and plentiful. Dwarf varieties in frames or under glass should have abundance of air, as too much heat and a close atmosphere are not conducive to fertility.

Turnips.—Some of these are sown in February and many in March; but those sown previous to this time may seldom prove profitable, as they are so liable to flower before bulbing. Now they are safe to form useful produce, and the Early Munich or Snowball should be sown. Give them good soil, a favourable situation. Make the drills 2 inches deep, 15 inches apart. Sow thin and tread the soil over the seed as firmly as possible. The latter operation is a capital one to make the bulbs come a good shape and clean.

Globe Artichokes.—The material which has been round the collars of these plants as protectors during the winter should now be forked into the soil about the roots. To secure large succulent heads—and no others are valuable—they must have rich soil, and if the mulching material has not much of this property left in it add more good manure.

French Beans.—Plants in pots are now bearing profusely. Give them plenty of liquid manure when the crop is forming. Throw away the old plants immediately they cease fruiting and supply young ones. No more need be sown in pots in warm houses; but seed may be planted in ordinary frames amongst good soil, and if glass lights are placed over them they will soon grow and bear much fruit before any which can be grown in the open. Osborn's is one of the best sorts to sow in a frame, as it does not grow tall and it is very prolific. Seed sown in a frame now will bear fruit by the end of May.

Tomatoes.—Plants of these, whether in beds or fruiting pots, must be restricted in growth. When growing in close warm houses at this time they are liable to make much superfluous wood, and would soon overrun a large space with unfruitful shoots, but these should be constantly cut away, and confine the plant to one or two bearing stems. These will bear a cluster of fruits every few inches and be more profitable than a large plant. Supply those bearing heavily with liquid manure twice weekly. Plants in 3-inch pots may be potted into 6-inch ones. Prepare a good batch of plants for planting in the open in May. These are better kept dwarf and not in too much heat.

Celery.—The main crop of this should be put in. If a slight hotbed can be made up to sow on have it by all means; otherwise sow seed in houses or pots, and bring the plants forward in pit or vinery. A gentle heat will do. Keep the young plants near the glass. Always water well. Early plants should now be standing 3 inches apart in small pots, boxes, or frames. Admit plenty of air, and avoid checking them in any way.

Young plants in frames, such as Cauliflower, Lettuce, &c., must have more air, as they should be hardy enough to bear planting in the open in a few weeks hence.

Leeks.—Sow a good patch of Henry's Prize, St. David, or Musselburgh in a rich soil, from which they can be conveniently transplanted by-and-by.

FRUIT-FORCING.

PEACHES AND NECTARINES.—*Earliest House.*—Where such varieties as Alexander and Early Beatrice are grown these have stoned and are swelling their fruit, to encourage which afford copious supplies of tepid liquid manure to the roots, and syringe twice a day, being careful to have the fruit dry before night, as moisture allowed to remain upon it some time will spoil the appearance of the fruit. Do not, however, raise the temperature until the other trees in the house have completed the stoning, keeping it as equable as possible until the trees have passed this critical process, which in the case of such varieties as Hale's Early, A Bec, and Royal

George, and of Nectarines Lord Napier and Advance, will not take long after this to be affected. In the meantime keep the temperature at 60° or a few degrees less on cold nights, 65° by day and 5° to 10° higher from sun heat. Give air early, but only a little, and gradually increase it as the day advances until the maximum is reached. Be careful in admitting front air, particularly in windy weather, as cold cutting draughts are likely to prove disastrous, if not fatal. Tie in young growths as they advance, leaving plenty of space in the ties, as tight tying frequently causes gum. Stop gross shoots when they have made about 15 inches of growth, or remove them altogether if likely to interfere with an equal diffusion of sap and growth throughout the tree. Keep laterals somewhat closely pinched, and avoid overcrowding as the greatest of evils in fruit culture.

Succession Houses.—Disbudding must be proceeded with, thinning the fruit by degrees, leaving those which are most favourably placed for swelling and colouring. Tie down the leading shoots and those at the base of the current bearing wood for supplanting it in next season's fruiting. In the house started early in January the fruits are swelling fast, and as they advance it will be advisable to remove most of those that will not be required. The thinning both of the fruit and of superfluous growths must be done gradually. A night temperature of 55° to 60° and 10° to 15° rise from sun heat will be suitable, losing no opportunity of admitting air, especially in the early part of the day, and close early with plenty of moisture in the house. Syringe twice a day, and see that there is not any deficiency of moisture in the inside borders. In the house started in February proceed carefully, judiciously, and progressively with disbudding and thinning the fruit, removing the growths on the strongest first, and the smallest fruit, especially that on the under side or back of the trellis.

Late Houses.—The late trees have been in flower some time; indeed, some of the trees have set their fruit. Air will need to be admitted very freely, as from the forward condition of the trees the fruit will otherwise ripen along with the third or fourth succession house, or the one that is usually started in March. Peaches submit to a low night temperature, providing the atmosphere is dry and frost is excluded, but a temperature of 50° by day should, if possible, be secured to them, as the organs of fructification are seriously impeded in their offices when subjected to prolonged cold. Keep a sharp look-out for aphids in all structures, and destroy them by fumigation, but be careful in its application so as not to injure the tender foliage. Where there is a great set of fruit, which is a common occurrence this season, remove most of that on the under side of the branches.

Figs.—*Early Trees in Pots.*—In dull sunless weather a certain amount of caution is necessary in the application of stimulants, for although the Fig be a gross feeder and roots rapidly, lessened supplies will be needed than when the weather is bright. Syringing in such weather will also need moderating, particularly in the afternoon, especially in houses that are close and low, for under no circumstances is it prudent to allow moisture to remain on the trees after daylight. In dull weather all watering should be performed before or directly after breakfast, by which time the heat of the day should be attained so far as that from fire heat is concerned, and on no account must the trees be allowed to suffer from insufficient supplies of water. Syringing in such weather must be performed between 1 and 2 p.m., doing it thoroughly, so that red spider may not increase. Attend well to the thinning and stopping of side shoots, as these play an important part in the second crop, but this more particularly applies to trees planted out than to those in pots, which last, however, must not be kept much crowded in the head, or the fruit will be poor and sparse.

Early Forced Planted out Trees.—Train all leading or terminal shoots in their full length where space remains to be filled. Do not, however, permit crowding, but keep the side growths duly thinned and stopped; as if formed into spurs they are an important factor in the second crop. Endeavour to obtain short-jointed wood by careful ventilation on all favourable occasions, and avoid a high night temperature, especially in cold weather. In ordinary weather the night temperature may be 60°, a few degrees less in cold weather or a few degrees higher in mild weather will not matter. Allow a rise of 10° from fire heat in the daytime, and keep at 75° or 80° through the day from sun heat. Give air at 75° or a very little on sunny mornings at 70°, increasing it with the solar heat, and close at 80°. Water the borders copiously, keeping the mulching moist so as to encourage surface roots.

Succession Houses.—Trees in inside borders should have good mulchings of short or half-decomposed manure, so as to encourage surface roots, giving a good watering with tepid water afterwards, and keep the mulching constantly moist, alike to keep the roots at the surface and to keep down red spider. Syringe twice a day on fine days, but early in the afternoon only on dull days. Stop side shoots at the fifth or sixth leaf, remove superfluous growths so as to avoid overcrowding, train and tie as growth proceeds, following the extension system if space permit and fine fruit is a primary consideration. Young trees intended for pots should be stopped at 14 to 15 inches from the base, and all the buds taken out from the axils of the leaves except two or three of the uppermost.

PLANT HOUSES.

Dahlias, Salvias, and Cannas.—If roots of these are placed in heat and covered with soil they will break freely, and may either be divided into several pieces with a shoot and small portion of roots attached, or firm cuttings of the two former may be struck in heat and will form the best of plants by the time they are required. The former are easily raised from seed sown in heat, and this is the cheapest method of securing a good variety of single Dahlias. Sow in pans of light soil and place in a hotbed.

Phloxes.—The early-flowering forms, such as Miss Robinson, Princess of Wales, Mrs. Downie, and others, are really beautiful when well grown

in pots. Young plants now in cold frames and well established in 3-inch pots should be transferred into 6-inch pots, using a compost of good loam, a seventh of decayed manure, and a little sand. Keep the frame close for about a fortnight after potting until they are rooting freely, when air may be admitted liberally. No attempt should be made to force them, or the growth will be weak and the trusses of flowers poor, but if grown under cool conditions and liberally treated they will be strong and produce very large trusses. In the conservatory or greenhouse when in flower they look noble, and they will come into flower some weeks before those in the beds and borders outside.

Tree Carnations.—Where choice sweet flowers are appreciated during the winter these should be grown, and in order to achieve the greatest success the plants must be propagated annually and grown on specially for the purpose. Dwarf sturdy cuttings will now be plentiful, and if taken off with a sharp knife just where they have issued from the old stem, they are sure under careful treatment to strike root with certainty. If these shoots are long, take off the top about 3 inches in length, which will do equally well. They should be inserted in pots, pans, or boxes, and after a good watering place bellglasses or handlights over them. After insertion they should be placed in a temperature of about 60°, where they will have slight bottom heat, and if well shaded from bright sun the majority will root. When in this condition air must be admitted gradually at first, until the covering they have received while rooting may be entirely dispensed with. As soon as they are rooted they should be gradually brought into a temperature, say 10° lower, by the time they are ready for placing in 3-inch pots, which should be done as soon as they are sufficiently rooted. Employ a compost of good loam, leaf mould, a little manure, and a liberal dash of coarse sand.

Carnation Souvenir de la Malmaison.—Plants that were raised by layering last autumn and have been in 3-inch pots during the winter in cold frames should now be placed in 6-inch pots. After potting return them to the frame, which should be kept close for about a fortnight, until they are rooting freely into the new compost. Afterwards ventilate liberally to maintain a dwarf sturdy growth. After the 6-inch pots are full of roots place them in others 2 inches larger and give the strongest plants greenhouse treatment, and they will be in good condition for the conservatory by the middle of June. By judicious treatment in pushing forward these plants or retarding them, a supply of their large flowers may be maintained until they can be gathered outside. Those for next winter and spring flowering will need the same treatment until the early part of June, when they may be placed in 10-inch pots and stood outside. For winter and spring flowering select those that are dwarf and most likely to produce shoots close from the base, as upon these the winter and spring flowers will be borne. The compost advised above may be used, and they should be carefully and judiciously watered until their pots are full of roots.

Border Carnations.—These are very useful for conservatory decoration, and a few of the strongest plants in small pots that have been wintered in frames should be placed into 5-inch and 6-inch pots. The beautiful white W. P. Milner, and the old crimson Clove are invaluable for this purpose, and will do well under cool frame treatment, coming into flower long before those in the borders outside. Not only are the flowers useful when cut, but at the season of the year when they bloom they are invaluable for association with other flowering plants.

Pinks.—Not to mention the use and beauty of these early in the season for forcing, they are unsurpassed for beauty when brought forward gradually under cool frame treatment, or in an airy greenhouse close to the glass. In 5-inch and 6-inch pots the old common White; Ascot, dark; and Mrs. Sinkins are, when well grown, scarcely equalled by any other dwarf flowering plants grown for decoration. The last is remarkably dwarf and floriferous, not being more than 7 or 9 inches in height when the flowers are expanded, which are as large as a Carnation and as sweet as a Clove. No garden should be without this variety, and where sweet white flowers are in demand in spring it should be grown in large numbers and forced in quantity. It is not quite so early-flowering as the old common garden variety.

THE BEE-KEEPER.

ABOUT LIGURIAN BEES.

As facts are far better than theories, and as your Journal is not prejudiced solely in favour of bar-frame hives and Ligurian bees, I write to give my testimony to support "W. B. C.," to express my sincere satisfaction at the point being so plainly stated, and to add my experiences.

The bad years about 1878 induced me to try the much-vaunted Ligurians, and, purchasing three queens from the best dealer, I had the satisfaction of introducing them, of watching the young bees appear, of handling them easily, and of noticing their apparent activity. This activity I soon discovered to be restlessness, and to be the cause of the extra feeding required for them compared with blacks. My experiences, however, were short owing to foul brood appearing in two out of the three hives. Immediately destroying these, and guarding all other hives with syrup and salicylic acid, stopped further loss from

that dreadful disease, though I lost my remaining Ligurian stock in the winter. It appeared remarkable to me then that foul brood commenced in Ligurian hives, attacked two of them, never affected my remaining blacks, and never appeared in my apiary before I introduced Ligurians.

Thus ended my first venture; but the repeated puffing of Ligurians by various bee authorities, and their vaunted praise in Mr. Cowan's excellent book, induced me to again try them. My experience thoroughly bears out that of others. My surplus from Ligurians is much smaller than from my ordinary English black bee, and my feeding to them is much more profuse. I ask your readers who are keepers of blacks and Ligurians, Which bees take honey down from supers first? and I confidently say that they will reply and bear out my experience, that the Ligurians are the first in autumn in spite of their nominal superiority in respect of second crop red Clover to take down their stores.

The introduction of Syrians, Cyprians, &c., negatively shows a want of satisfaction with the Ligurians, and I wish that our excellent British paper as England's authority on bees would approach this subject with less bias, and at the same time admit more fully the certain good points of skeps and Stewartons. To assist bee-keeping as a general pursuit, and especially for the cottagers, it is an error to be too closely attached to bar-frame hives and Ligurian bees. I have long wished for this exposure of Ligurians, and especially when I have been judging at local shows and seen the novice prizing his Ligurians, and found him deaf to any idea of mine that the change would not be worth the cost. Worth the cost! I would give more for a black queen than for a Ligurian queen: I would have one in my apiary, I would not have the other. —THE WELSH BEE-KEEPER.

WHILE I can fully endorse most of what "W. B. C." has to say against these bees, I must demur against his classing all foreign bees with them, by doing which he falls into the same error he commences in charging the late Mr. Pettigrew with, for condemning these bees before he had tried them, for, according to his own showing, he has tried no foreign bees except the Ligurian. I have also tried these bees, and have even a worse report against them than "W. B. C.;" and if anyone left me a legacy of fifty stocks the first operation I should perform would be to kill all the queens right off. I would not even sell them, because I should feel to be taking good money for what I consider a worthless thing.

I have also tried another foreign bee—the Syrian, which seems to realise all my wishes, and I have nothing but praise for it: but it has certain peculiarities one must understand, its general characteristics being the very opposite to blacks. They must on no account be smoked, they never rob, will never gorge themselves, will breed twice the number of bees, and always be the first to work in a morning. All breeders and hybridisers know that by uniting two extremes the fruit is mostly a pleasing one, and a Syrian queen mated with a black drone is no exception. I can cite a case where £20 profit has been made in one season in this country from one stock; another where the increase was £7, and each gathered sufficient to winter on, while twenty black stocks failed to swarm and had to be fed for winter. Imported queens of this race cost 22s. each, and, having had a dozen of them, I would cheerfully pay as many pounds if I could not get them for less.—HALLAMSHIRE.

AT WHAT AGE DO BEES GATHER HONEY?

ACCORDING to the experiments of Mr. G. M. Doolittle a young bee does not gather honey until it is sixteen days old. I had come to the conclusion, many years ago, that in about thirty days from the laying of the egg a young bee would be gathering honey, if there was a good yield.

As I received some very fine yellow Italian queens from a breeder in Maryland a few days after reading Mr. Doolittle's article, I thought I would make some similar experiments, to see what the results would be with me. Consequently I introduced a fine yellow queen into a colony of native bees. In about forty-eight hours afterwards the queen began to lay vigorously, and in twenty-one days thereafter the little "yellow boys" were hatching out of the cells in great numbers. In five days more some of these young yellow bees brought little pellets of pollen; and when seven days old, I found by crushing them as they dropped upon the alighting board, that quite a proportion of them had their sacs filled with honey. When nine days old they were gathering honey as freely as any in the hive, and came as well laden as the older bees.

There was no possibility of a mistake in the matter, for before the hatching of brood from the new Italian queen not a yellow bee could be found in the hive. In fact, most of my bees are of the common kind, and the colony experimented with was especially free from any yellow-banded or hybrid bees.

This experiment was made during an abundant honey yield from bass wood. In such a case undoubtedly bees would work much younger than when the honey flow was less. In our spring management this question becomes of some importance, as we would like to know about when

the young bees, which we have taken so much pains to increase by spreading brood, &c., will be ready to go to work for us.—N. M. CARPENTER (in *American Bee Journal*).

BEES, HIVES, HONEY, &c., AT THE INTERNATIONAL HEALTH EXHIBITION.

THE Executive Council have resolved to apportion a limited space for an exhibition of honey and the various articles used in its production. The entire arrangement and management of this department has been placed in the hands of the British Bee-keepers' Association, the Committee of which are very anxious to arrange for a full and comprehensive display of the honey products of the United Kingdom.

The Committee invite exhibits under the following heads:—1, Pure honey. 2, Hives of bees at work. 3, Specimens of the most approved hives and appliances used in modern bee-keeping. 4, Objects illustrative of the natural history of the honey bee and its kindred varieties, also of bee flora. 5, The means of detecting adulterated or spurious honey, with analysis of impure or adulterated honey now sold in the markets. 6, The beverages in which honey forms an important constituent, with the recipes for making the same. Every information may be obtained upon application to the Secretary of the British Bee-keepers' Association, Mr. J. Huckle, King's Langley, Herts, R.S.O.

TRADE CATALOGUES RECEIVED.

E. Webb & Sons, Wordsley, Stourbridge.—*Catalogue of Special Manures*
Richard Smith & Co., Worcester.—*Catalogue of Farm Seeds*.

* * All correspondence should be directed either to "THE EDITOR" or to "THE PUBLISHER." Letters addressed to Dr. Hogg or members of the staff often remain unopened unavoidably. We request that no one will write privately to any of our correspondents, as doing so subjects them to unjustifiable trouble and expense.

Correspondents should not mix up on the same sheet questions relating to Gardening and those on Bee subjects, and should never send more than two or three questions at once. All articles intended for insertion should be written on one side of the paper only. We cannot reply to questions through the post, and we do not undertake to return rejected communications.

Books (A. B. C.).—"Select Ferns and Lycopods," and "Choice Stove and Greenhouse Plants," both by Mr. B. S. Williams, and published at the Victoria and Paradise Nurseries, Upper Holloway, are useful and practical works. (F. L. S.).—The work on stove plants named in the preceding reply will suit your purpose, and Dr. M. C. Cooke's "Manual of Structural Botany," published by Bogue, St. Martin's Place, Trafalgar Square, is a cheap elementary book.

Violets (J. O.).—We thank you for the beautiful bunches of Violets, and in answer to your inquiry inform you that the flowers are of good average quality both in size and colour. Although some grown in the south are larger still more are smaller, and you have good reason to be satisfied with your productions. We presume you do not grow Marie Louise or odorata pendula of New York. They are very superior forms of the Neapolitan, and worth your attention.

Earth Closet Manure (R. H. R.).—You are right in your reference to the bushel. It is 32 quarts. No one can answer your question as it is put, because it is impossible that the strength of your tank manure can be made clear. We should not like to risk even half a peck to a square yard at first, and then should proceed experimentally. Try it on Cabbages in different quantities, and note the results. This will be the best and safest course you can adopt. The ashes are of little or no value, sifted garden soil being far superior as an absorbent.

Liquid Manure for Fruit Trees (N., York).—As your Apple trees are strong, young, and healthy they would probably not be benefited by liquid manure, which could more profitably be given to older trees that are more or less enfeebled or to vegetable crops. It may be given at the present time and at intervals during the season to whatever trees or crops may need manurial assistance.

Vines in Pots (R. H. R.).—We are glad to hear of your favourable prospects. If you carry out the system of potting in the spring as detailed by Mr. Bardney in the same careful manner as he practises it, and you are as successful as he is in fruiting Vines in pots, you will have good reason to be satisfied. We have seen Grapes on Vines in pots grown by Mr. Bardney much superior to many crops we have inspected on Vines established in borders. We shall be glad to have your experience in due time.

Insects on Roses and Pelargoniums (E. W., Brighton).—Various insecticides are equally good for destroying aphides on these plants. Nico-

tine soap, Gishurst, or fir tree oil, each dissolved at the rate of 2 ozs. to a gallon of water, will extirpate the insects without injuring the plants. Syringing the plants and then dusting with tobacco powder will have the same effect. Fumigation is also safe and effective if done before the plants are much infested; in fact, it is true economy to either fumigate or syringe the plants occasionally to prevent the appearance of insects, this being the practice of the most successful cultivators.

Disbudding Vines (J. Watson).—As you say there are a "dozen buds breaking from a spur—quite a cluster," you may safely remove all but two or three at once, removing the strongest and best placed. These you may allow to extend until you are able to determine which will produce the best bunches, and when these laterals are safe you may take off the others, as only one will be required on each spur, the spurs being at the least a foot apart. As a rule far too many laterals are left on Vines by those who fail to grow good Grapes, and the subject of disbudding demands great attention at this season of the year. We can no more tolerate superfluous growths on Vines than weeds in a flower pot, for both are robbers, hence injurious. Disbud your Vines at once.

Planting Currant Trees (D. E.).—It is late to transplant them now, especially as the season is so early and the growth advanced. We, however, had occasion to remove some young trees last week, when several of the leaves were expanded. We were careful to keep the roots quite moist in transit, and by planting carefully and sprinkling the foliage daily the leaves remain quite fresh, and every tree will grow. Had the roots been permitted to get quite dry, and the foliage been allowed to shrivel, every tree would have died.

Ringling a Pear Tree (J. H.).—Your adviser was a quack, and it appears you have found out he is "no gardener." You will also find out that the operation he has performed will not benefit your tree. It may, however, not seriously injure it, as luckily the ring cut out is narrow, and if the tree is vigorous new bark will grow over the space from which the old has been removed. If the Pear is a good variety, and the tree grows well and is not cankered, we should not graft it, but cut off the old spurs and secure young wood. If the variety is not good, then grafting would be advisable, but it is too late for this now unless you have dormant scions. You had perhaps better let the tree alone, and write us again in the autumn.

Drying Amaryllises (G. P.).—We are aware that it has been recommended not to dry off the plants in the winter, but to keep the foliage green, but not growing, and we have no doubt that plants thus treated were satisfactory and flowered freely; but we also know they will succeed equally well, if not better, if the growth is well ripened in the summer in a high and dry temperature, gradually withholding water in September, and not giving a drop from October till February. In this case the foliage is removed entirely, and the pots containing the bulbs can be stored under a stage in a warm house. It is in this way the plants are treated that are now flowering in Messrs. Veitch's nursery at Chelsea, and finer examples of culture have never been seen.

Layering Chrysanthemums (E. Lawson).—The process is perfectly easy, and with ordinary attention you need have no fear of failure occurring. Plant a few old plants out of doors in a row; let them grow as wild as they choose till the month of July; then take as many pots as plants are required, and plunge them, filled with some rich soil, into the ground, at such a distance from the plants growing in the ground as will allow the tops only, when bent down, to reach the pots; bring them carefully down, and peg each branch firmly in the soil. Leave about 2 inches of the top out of the soil. If the shoot is branched it is well, but if not it must not be topped, because there is some danger that the layer may continue to grow and not flower if topped so late in the season. The aim of this mode of propagation is to make them flower when very dwarf; and, therefore, the layer should have buds upon it just visible at the time when the layering is performed. Keep the soil in the pots moderately moist till roots are formed, and after that water more freely. When it is certain that the layers have made plenty of roots cut them off from the parent plant, and remove them into a frame or pit deep enough to receive them. Should they flag during the day, give a sprinkling of water, and shade for a day or two till they recover; then give air and water freely. They will then be nice plants, about a foot high, with, perhaps, six or ten flowers on each.

Mushrooms (W.).—As you can only obtain such a small quantity of manure you must not expect great results. If the material is very good, and you can procure some older manure and leaves, you may first have a layer of them—say 6 inches thick—and made firm; then a further thickness of 6 inches of the prepared manure would suffice, and altogether you might have a good-sized bed, which, being in a shed, we should have flat and 3 or 4 feet wide. The bed should be a foot thick when pressed firmly. We have had excellent Mushrooms by inserting spawn in declining hotbeds; but whether they would grow in yours we are unable to say, not knowing its condition nor the use to which the bed is to be afterwards applied. If it is an old spent bed that was made last year it will not answer for growing Mushrooms this. If it is a bed made this spring, spawn inserted in May or June will result in the production of Mushrooms in the autumn, provided the temperature and condition of the bed as regards moisture be favourable for the spread of the mycelium.

Spawning Mushroom Beds (A. W.).—When the heat of a bed is declining, and a thermometer with its bulb inserted 2 inches below the surface of the bed indicates a temperature of 80°, lumps of spawn may be safely inserted; but not if the temperature of the bed is still rising, as it may increase to such a degree as to kill the mycelium. When the spawn is inserted it is advisable to cover the bed with litter to prevent the surface drying, also the heat of the bed can be kept nearly uniform by regulating the thickness of the covering. If a thermometer laid on the surface under the litter registers 60° it will be quite right, a degree or two above or below that temperature not being material. The running of the spawn is not "palpable on the surface," or it ought not to be, before casing the bed with soil. If the manure is in good condition, and the spawn good also, the latter will on examination of a lump or two in three or four days to a week after insertion be found to be moving, the mycelium spreading and taking possession of the surrounding manure. The soil should then be added and the beds covered

as before to prevent evaporation from the surface. If the covering is too thick, and the surface of the bed kept too warm—approaching 70°—the spawn will probably soon be too “palpable” on the surface, its presence there in large quantity not indicating a productive and long-lasting bed. Warm water is not, as a rule, used by market gardeners in watering Mushroom beds, except it is warmed by exposure to the sun in tubs or tanks. Under good management they do not need watering in cold weather, as if the manure and soil are properly moist when used, sufficient moisture can be conserved by the coverings and damping the litter as may be needed.

Syringing Vines (*J. T. S.*).—No rule-of-thumb practice such as syringing twice a day, or once a day, can be laid down. Many persons grow excellent Grapes without syringing at all, others produce them by indulging freely in the use of the syringe. It is safe until the growth has fairly started to syringe the rods once or twice a day according to the brightness of the weather, the afternoon syringing always being done soon enough for the Vines to dry before night. On dull days Vines do not need syringing, nor do they after the foliage expands if a moist yet buoyant atmosphere is maintained. Systematically syringing Vines with water that contains much lime is in our opinion decidedly more injurious than beneficial.

Heating Melon House (*Idem*).—Three rows of hot-water pipes enclosed under the bed are excessive—that is, if the water circulates properly and is heated sufficiently for affording the requisite top heat from the pipe along the front of the bed; and if the water does not circulate freely there has been a mistake somewhere in arranging the pipes or setting the boiler. The distance of the pipes from the bed is not material, but so far as we understand your case we should certainly have apertures in the side of the chamber for allowing quite half the heat from the pipes to warm the atmosphere of the house. If you have placed the whole thickness of 12 to 14 inches of soil in the bed at once you have acted contrary to the practice of all good gardeners and their teachings in this Journal. A thin layer of soil is all that is needed at first, say 2 to 3 inches. Mounds are then formed containing half a bushel of soil or little more at suitable intervals for planting. In this way the soil is soon warmed, but by placing in the whole bulk at once the heating of it must necessarily be a much slower process. As the roots of the plants protrude through the mounds they are covered with inch layers of warmed soil until the prescribed space is occupied, and with otherwise good management the plants grow with great rapidity.

Names of Plants (*H. B.*).—*Scilla bifolia alba*. (*G. C. S.*).—The yellow flower is *Doronicum caucasicum*, the Caucasian Leopard's-Bane. The other is *Saxifraga ciliata*. (*E. M. P.*).—The plant is a fungus known botanically as *Cyathus vernicosus*. (*J. B.*).—1, *Asplenium cicutarium*; 2, Too much withered; 3, *Dendrobium Pierardi*. (*J. McN.*).—*Compactia falcata*. (*H. T.*).—*Andromeda floribunda*. (*A Constant Reader*).—1, *Zephyranthes Treatiae*; 2, *Gasteria variegata*; 3, *Asplenium bulbiferum*; 4, *Pteris tremula*; 5, *Nephrodium molle*. (*R. B.*).—1, *Narcissus pseudo-Narcissus*; 2, *Narcissus odorus*; 3, *Narcissus incomparabilis flore-pleno*. We have received some other flowers, which, being unaccompanied by the name of the sender, cannot be named. (*E. S.*).—1, *Asplenium marinum*; 2, *Adiantum ethiopicum*; 3, *Pteris argyrea*; 4, *Davallia canariensis*. (*W. W. K.*).—1, *Cheiranthus Marshalli*; 2, *Erica Cavendishiana*; 3, *Maranta zebrina*. (*X. B.*).—1, a fine variety of *Dendrobium nobile*; 2, *Dendrobium Wardianum*; 3, *Odontoglossum vexillarium*; 4, *Masdevallia Lindeni*, 5, *Phalaenopsis Schilleriana*. (*R. S. T.*).—*Aubrietia deltoidea Hendersoni*.

Flowers for Bees (*A Subscriber*).—The following are amongst the best for affording honey and pollen:—Crocuses, Hyacinths, Mignonette, Wall-flowers, Sweet Alyssum, Candytuft, Beans, Melilot (*Melilotus leucantha*), *Epilobium angustifolium*, and Borage, the last three being excellent. The Scabious and *Nepeta Mussini* are also very good. Fruit blossoms of all kinds yield much honey, as do such wild plants as Clover, Mustard, and Heather. The only reply we are able to give to your second inquiry is that fowls of all kinds are advertised in *Poultry*, which is issued weekly, price 1d. We never recommend dealers.

COVENT GARDEN MARKET.—MARCH 26TH.

No alteration to quote from last week, with the exception of Strawberries, which with a good supply and little demand are reduced in value. Grapes also inclined to go back.

MILDEW IN WHEAT CROPS.

THIS subject is extremely interesting and important to the home farmer, and whatever we may have learned during our connection with practical farming, yet scientific men in their pursuits have proved so observant and persevering that they have been enabled to give us information upon the subject which it was not easy for us to obtain without them. Mildew in Wheat is a very serious impediment in farming, and although it is a question of seasons and weather, yet it may to some extent be mitigated by certain modes of cropping, manuring, and cultivating the land. On some soils in certain climates Wheat suffers more than in others. It is also known that the rotations of cropping have an influence which is not yet understood by the majority of farmers. It is owing to these circumstances that the very excellent essay published in the Royal Agricultural Society of England's Journal, Part ii., for the year 1883, furnished by Mr. W. C. Little of Stag's Holt, March, Cambridgeshire, will prove such a valuable and timely addition to our agricultural literature.

In the course of this essay the author writes as follows:—“Among the numerous diseases which affect the cultivated crops of this country there is probably not one which is more disastrous to the farmer than Wheat mildew. Potato blight and Hop mould may sometimes destroy crops which are more costly, and potentially much more valuable than a crop of Wheat; but growers of these crops have generally some compensation for their losses. Occasionally they make large profits, and with them the part is often greater than the whole, for not unfrequently a deficient crop realises more money than a full crop would have done, because the price has risen in consequence of the short crop. But the grower of Wheat has no handsome profits to fall back upon, and the foreign supply prevents that advance in price which might in some degree make up for a diminished yield. The yield of his crop may be reduced 75 per cent. by mildew, and what remains is scarcely saleable. Widely spread as this disease is, and great as is the damage done by it, there would seem to be many farmers who have never suffered serious injury from it, and some who do not even know what it is. It may therefore be desirable to give some idea of what a mildew year means in the east of England. In 1881 nearly all the white corn crops in the low lands of Cambs, Hunts, Lincoln, Norfolk, and Suffolk were more or less mildewed. Many crops of Wheat were almost entirely destroyed, the Oats were greatly diminished in yield and quality, and in some cases the Barley was considerably injured. The district most severely injured may be defined roughly by the following boundary: From Cambridge, N.E., to Mildenhall, thence north to Stoke Ferry, thence W. by Downham Market to Wisbech, thence N.W. to Spalding, thence S. by Peterborough to Huntingdon, and S.E. to Cambridge again. This area comprises at least 600,000 acres of land, a large proportion of which is under the plough, and Wheat is the staple crop. Probably 25 per cent. of the total area, or 150,000 acres of Wheat, are harvested every year in the district described. In the middle of the month of July, 1881, there was on all the best Wheat lands of this district the promise of a fine crop, which seemed within the grasp of the farmer. Then an attack of mildew came, and the consequence was that the crop of that year was one of the most wretched ever gathered. At harvest many of the best of those crops, which would under more favourable circumstances have yielded from 40 to 48 bushels to the acre, produced only 20 bushels, and some of the very best land yielded only 12 bushels of Wheat, which weighed only 43 lbs. a bushel.”

We have seen such visitations as the above in various districts, but particularly in 1853, 1860, and 1879, with others at a more remote period, and if we tell the truth of our own crops in these years Mr. Little's statement would as nearly represent our own as possible. Physicians, when they have to study disorders which affect mankind or the live stock of the farm, do not content themselves with a diagnosis of the disease; they proceed to ascertain what are the conditions under which the disease is generated or propagated, and they further inquire whether any habits of life, any inherited predisposition, any accidental causes, either spread the disease or make it more destructive in its character. Why should not the same plan be employed in the case of plant diseases? In answer to this question let us refer to those scientific men who are capable of reply, and in doing this we must notice Mr. Carruthers' paper on the subject contained in last year's Journal of R.A.S.E., vol. xviii, pp. 495–503, 1882; and also of a paper contributed to the *Gardeners' Chronicle*

n August, 1882, by Mr. C. B. Plowright of King's Lynn, who is well known as an authority on British fungi.

Mr. Little writes, "Wheat mildew is caused by a parasitic fungus, known as *Puccinia graminis*, which attacks both Oats and Barley, as well as many of the natural Grasses of this country. This parasite lives within the cellular tissue of the plant, sapping its vitals, and converting to its own use the sap which should nourish and mature the grain. The presence of this fungus in the infested host plant is evidenced only by its fruit or reproductive organs, which burst through the cuticle and appear in red and black patches, disposed in rather irregular lines on the leaves, straw, or chaff." The life history of this fungus is remarkable, as, stated by Plowright, "it has no less than five kinds of reproductive forms . . . *Æcidium*, *Spermatogonia*, *Uredo*, *Puccinia*, and *Promycelium*."

Mr. Carruthers says, "The injury done to the Wheat by the rust and mildew arises from the fungus appropriating to its own use the elaborated juices of the Wheat. Fungi are plants without the green colouring or chlorophyl which exists in other plants, and they are consequently unable to separate the carbon from the carbonic acid gas of the air—that is, to manufacture plant food from the raw materials on which plants live, they therefore depend on the already prepared food of the plants on which they are parasitic. The fungus in its rust stage takes possession of the growing plant, and weakens it so far as it appropriates the material which was intended to build up the growing Wheat plant. A few bright sunny days arrest the progress of the fungus, and vigorous plants overcome the attack without any real injury. When, however, the mildew appears at a later stage in the life of the Wheat the conditions are entirely changed. The story of the fungus suggests important considerations to the farmer. First, it is certain that the brown spores of the mildew which remain attached to the straw after harvest are the means by which the fungus retains its vitality through the winter. Converting the straw into manure does not destroy the spores, but rather provides in the spring the conditions fitted for their germination. It may be recommending a serious destruction of property to suggest the burning of mildewed straw, but fire is the only agent that will effectually destroy the spores."

This closing part of the quotation from Mr. Carruthers' paper is a very serious matter for the consideration of practical farmers, as it will be seen immediately that this kind of straw will not sell in towns, nor is it healthy or nutritious food for stock, even if converted into chaff, for in that state it would be as unpalatable as whole fodder. It is therefore very clear that the only use which can be made of mildewed straw is to litter the stables and cattle boxes, and turn it into manure, which brings us to a point for further consideration, How the manure can be used without injury to succeeding crops.

(To be continued.)

WORK ON THE HOME FARM.

Horse Labour.—Horses are now engaged in the busiest period of the year, and in various instances, when the first really dry weather occurs, it is frequently difficult even for the most experienced farmers to say which work should be done first. We must, therefore, now suppose that the planting and drilling of Beans and Peas is now over, and that attention must now be given to Barley seeding. One word, however, as to the drilling of Peas. It is a common custom to drill both early or late Peas at about 20 inches, so that horse-hoeing may be done between the lines and hand-hoeing in the lines. One of the best farmers we know contends, as it is his practice, that the Peas should be drilled at 12 inches apart between the rows and hand-hoed only, for it is contended that unless the land be foul with couch grass horse-hoeing is not necessary, if the land is in good heart, and that as soon as the Peas begin to spread, they reach each other and effectually overpower the annual weeds. The best malting samples of Barley are usually grown after early sowing, but the condition of the land best adapted for the crop is a thoroughly disintegrated soil, so complete that a quick rooting for the Barley will be reduced to a certainty; but on the other hand the land should not be made too rich, for if the Barley goes down, lodged, or laid, it is hopeless to expect a malting sample. There is, however, another point worth attention—the distance between the rows if drilled. Now, if the land is rich and in high tilth the rows should be 12 inches apart instead of 7 inches, and two bushels of Barley per acre is an abundance of seed if we are to expect malting Barley. There is another point of importance, that as the value of Barley depends upon an even sample, that it never ought to be sown after roots fed off by sheep, for in consequence of the changeable climate the land can seldom be all alike in condition, even in one field, owing to the tread of the sheep and their irregular lying or folding in variable weather. Therefore we should seed such land in such condition with drege, and if good Barley for malting is required let it be screened and separated from the Oats, and in nineteen cases out of twenty a good malting sample will be the result, whereas Barley grown by itself in a speculative crop not only from adverse circumstances as to weather, &c., but also in consequence upon light soils from the frequent repetition of the crop. The land should now be prepared for Mangold, and the sooner the seed can be deposited in good-conditioned land the better, for the April month is the best seed-time; nor have we ever seen

the young plants as they appear injured by the night frosts of the May month which sometimes occur. The seeding for Carrots is a different matter, for if the land is continued under preparation, or even drilled with Carrot seed after a crop of *Trifolium*, &c., in the second or third week in May, it will save one hoeing, and go far to insure a better plant of Carrots; and as a matter of economy generally we have found it not only a desirable plan, but it insures a better plant as a rule. Cabbages for cattle should now be drilled on the stretch with yard dung or otherwise Peruvian guano, 4 cwt. per acre, sown broadcast, and stretched or ploughed into the stretches, and these can be drilled with seeds of Champion Cabbage with the hand-garden drill or the Scotch stretch drill. When the plants are a good size for hoeing leave the strongest, and the other plants will do for planting with the spade on land after green or catch crops as fast as the land is ploughed.

Potatoes for the main crop should now be set. We are planting the *Magnum Bonum* variety, for they are not only good for sale to the consumers but good croppers, and good keepers into the following spring, and are at the same time seldom attacked with the disease. We, however, are planting small tubers; but if they are to be cut into sets for planting they should be cut between the buds at one end down the tuber lengthways, and should furnish each tuber only two sets, as they have but few buds or eyes, and these are for the most generally at the small end of the tuber.

Hand Labour.—The men, and women too, will now be busy, and should be employed, the latter for the purpose of being in reserve for weeding in the grass and corn as soon as ready. The Clovers are this year forward, and on all forward soils weeding by hand labour may now be done with advantage, for weeds such as Docks and Thistles may now be plainly seen. Planting Potatoes will be going on as work for women; men being employed either in spreading dung, which, being done at planting time, the women may rake it into every third furrow simultaneously with the ploughing; if artificial means are used they should be mixed with damp ashes and strewed into the furrow and covered in with the sets.

Live Stock.—Dairy cattle are now mos'tly in the fields and grass lands, the latter being very early and fit for feeding this year owing to the mild winter and spring hitherto. We prefer, however, generally to reserve for the cows as they calve the best and forwardest grass. On the hill farms the root crops are holding out well; there is also generally a store of Mangold roots for feeding later on with Clovers and Sainfoin, and these will be found almost invaluable in the event of a dry summer, for it will keep the lambs in good and growing condition. For the present, however, we have the water meadows for use, which never were better. The same may be said of the catch crops, such as Rye or Rye and Vetches, also *Trifolium* and Italian Rye Grass, for these latter-named Grasses are invaluable upon hill farms, especially on some which are out of reach of water meadows. The quantity of roots in store are a safe food for fattening cattle in the boxes and stalls, and may hold them on until the end of June and July, when moderately sized bullocks, not too fat, are sure to sell well, notwithstanding our foreign importations, because this in dead meat is not so available in the heat of summer, although it may have kept well by refrigerating during the transit to this country. Fattening sheep should now be sold, because they will otherwise get too fat and too heavy for the butchers in hot weather. It is doubtful also whether they will pay for shearing yet, for the wool trade is not very encouraging.

OUR LETTER BOX.

Cows (V. C.).—There is no general complaining that cows do not prove in calf this year, except in some cases when they have suffered from foot-and-mouth disease it is the case. As regards your cows you do not say when they had this disease, and therefore we cannot say they are likely to be barren in consequence. We should think it more likely to be from inattention in management; but we advise you to consult a veterinary surgeon, who would inquire as to all the circumstances of the case and advise you accordingly.

REMARKS

16th.—Very fine all day, and quite summerlike.
17th.—Fog early, then very fine and warm.
18th.—Fine throughout, but cooler.
19th.—Dull all day, and cooler.
20th.—Fine bright day; slight shower about 3.30 p.m., and a little rain in night.
21st.—Cloudy early, then brighter, but spots of rain occasionally.
22nd.—Cold in morning; a fine day, but overcast occasionally.
A fine week with considerable range of temperature, the early part being as warm as the middle of May, and the last day with a frost.—G. J. SYMONS.

PERPETUAL CARNATIONS.

IF we except Tea Roses it may safely be asserted that Carnations are the most serviceable and generally popular flowers in cultivation, this being especially the case with the section known as Perpetual or Tree Carnations. At the same time, fully appreciated as they are, they are by no means generally well grown, neither do they receive such good treatment as their merits entitle them to. Thanks to Mr. Taylor, who when at Longleat not only grew them to perfection, but also instructed many others, myself included, we now thoroughly know their special requirements.

As was pointed out to an inquiring correspondent on page 236, to have Carnations good when most required—viz., during the winter months, the stock of plants should be raised annually, it being found that vigorous young plants are superior in every respect to old plants, no matter how well the latter may have been treated. Cuttings may be struck any time during January, February and March with a fair chance of their being grown into strong flowering plants, but if struck much later the plants will be both smaller and later in flowering. Supposing no cuttings are to be had, would-be growers should procure a few strong plants from a nurseryman of good repute, and it is advisable when ordering to state that they are required for furnishing cuttings. When received they should be stood in the lightest position in a greenhouse or in a house where but little heat is given, carefully supplying them with water and removing all bloom buds, the object being to induce the formation of strong shoots for cuttings.

The tops of strong leading growths are naturally selected by the inexperienced, but these are not the best and will seldom form such good branching plants as those from side shoots. The latter are usually slipped off with as little injury to the main stems as possible, and require but little trimming, the removal of the lowest pair of leaves, which are usually small, sufficing. Any cuttings, however, much above 4 inches in length may well be shortened to a joint much as we would any softwooded plant, but there is no necessity for mutilating or shortening the leaves. Those who have a considerable number of cuttings ready at one time may strike them in boxes not less than 6 inches in depth; these being properly drained, filled to a height of 3 inches with fine loamy sandy soil, and surfaced with silver sand. The cuttings to be dibbled in firmly and about 2 inches apart each way, be watered in and covered with squares of glass, which, if made air-tight by having strips of paper pasted over all the edges, will further assist the cuttings in striking. The boxes may be placed either on a gentle hotbed or on moist stage in a forcing house where no strong fire heat or bright sunshine will affect them. If a few cuttings only are available at a time, these may be inserted thinly round the sides of small pots, and stood or plunged either in a propagating case or a Cucumber frame. Last season our cuttings did not strike so readily in pots, owing to the attack

of some fungus generated in either the loam or leaf soil, which made the plants late. This season we are using peaty soil and large well-drained pots and pans, covering the cuttings with bellglasses, the results being perfectly satisfactory. The soil in the pots or boxes should never be allowed to become dry, and the cuttings require to be shaded from bright sunshine. They take about three weeks to strike.

Directly the cuttings are rooted they commence growing, and to prevent their becoming drawn and weakly gradually remove the glass, exposing the plants to the light and air, and pot them before the roots become much interlaced. The greatest care should be exercised in potting, as the roots are exceedingly fragile and may easily be broken from the stem. We prefer to cut or dig out the cuttings rather than shake them out of the boxes or pots, as in this manner every plant has a small ball of soil about the roots, and little or no check is experienced from the operation. The strongest plants may be placed singly into 3½-inch pots and the more weakly into pots a size smaller, employing a compost consisting of two parts of fine loam to one of sifted leaf soil, with the addition of a little silver sand. The plants should be returned to the shelves or be placed near the glass in a house where a temperature is maintained, say, from 50° to 60°, with the usual rise with sun heat. At this stage particular care should be taken to prevent rapid weakly growth, as they cannot well be kept too dwarf so long as no actual check either from dryness or coldness is experienced. In the case of very strong early plants, or if the plants be much drawn, it is advisable to stop them once; but all that are branching or late struck are best unstopped, or otherwise they will not flower freely until the spring, and perhaps not then.

Before they have become root-bound a shift should be given them, and this in our case is usually into their largest pots. The size of pot given depends upon the vigour of the plants and the habit of the variety. In all cases it is better to underpot rather than overpot Carnations. The majority of ours, however, are flowered in 8-inch and 9-inch pots, but those of moderate growth, such as Miss Jolliffe and A. Alegatière, are either flowered in 6-inch pots or given a second shift. Those late struck may be placed three in an 8-inch or 9-inch pot, and will do better in this manner than if flowered in small pots. I am aware that great numbers of well-flowered plants find their way into the markets growing in 5-inch pots, but for continuous blooming this size is too small.

The compost which appears to suit them well consists of four parts of roughly broken strong turfy loam to one each of good half-decayed stable manure and sifted leaf soil, adding road grit or silver sand freely, and a sprinkling of bone meal. It is not advisable to add any powerful artificial manure to the compost, but it may with advantage be given to them at the flowering period, all the pots to be clean and well drained, and the soil made rather firm to suit the fibrous roots.

The plants after potting should still be kept under glass, not in strong heat, but preferably in a cold frame or pit where they can be kept rather close for a few days. Gradually, and before they become at all drawn, give more air. Towards the end of April and during May the lights are best drawn off on fine warm days, and well tilted in wet weather. When well established give all air possible, and by the end of May the plants may be stood on a bed of ashes in a sunny but sheltered position in the open air. In cold wet districts, and in all cases where there are few roots, the plants are best kept in frames, these being blocked up off the ground so as to admit plenty of air, and the lights pulled off during bright and dry weather. Miss Jolliffe and Souvenir de la Malmaison are the most susceptible of injury from cold rains, and these we rarely move from the frames. All the leading growths should be kept carefully supported, as if once they get crooked they cannot be safely straightened. At Longleat they used to support all bushy plants with birch branches much as we

would pots of Kidney Beans, and this plan we also imitate with advantage.

Towards the end of September, or before wet and cold weather sets in, all the plants should be housed; and as a considerable number of them will have many buds ready to expand, the season may be said to commence from that date, and will last till late in May, even later if house-room can be afforded them. A light airy lean-to greenhouse is the best position for them during the winter, as they require all the light and sunshine possible. In such a house even they must not be crowded together or mixed with other plants, as this, and especially if the plants are at all shaded, results in the formation of little else but long weakly growth. Given all the light possible and air on all favourable occasions, a temperature maintained by fire heat when necessary, ranging from 45° by night to 55° by day, with a proper supply of moisture at the roots, and they will yield blooms in surprising quantities. They may easily be injured by overwatering, especially when first repotted or if badly rooted. Occasional supplies of liquid manure obtained from the farmyard must be given if large blooms are expected, and good substitutes for this are Standen's, Clay's, or other makers' fertilisers as advertised. The former should be freely diluted and the latter used sparingly, either dissolved in water or sprinkled on the surface of the soil and watered in.

Carnations are rather liable to be infested with aphides, especially if in an unhealthy state. Fumigating with tobacco paper is the simplest and most effective remedy. Nicotine soap, quassia chips and soft soap, Hudson's extract of soap, tobacco powder, and other well-known remedies all prove destructive to green fly, and either may be tried by those objecting to fumigating. Red spider also occasionally attacks Carnations and must be kept down by syringing both during hot and dry weather, and when much fire heat is employed.

The most generally serviceable varieties we have here are Miss Jolliffe, flesh colour; Belle Rose, bright rose; Purity, pure white; and Souvenir de la Malmaison, blush white, all being free bloomers and highly scented. The latter is the most valuable, and we are cutting fine blooms of it nearly all the year round. In this case the old plants are retained, these flowering nearly at all times, and which they are encouraged to do till worn out. The spring-struck plants commence blooming the following spring, and these give us much the largest blooms. By way of variety we grow a limited number of other sorts, such as Andalusia, yellow; Laura, pink; both having large fringed flowers, as well as being of vigorous growth; Juliet, white, flowers large and plant vigorous; Sir Evelyn Wood, rich crimson, vigorous, but more dwarf than the foregoing; L'Hermine, white, of medium growth; Annie Williams, pink, of moderate growth; Mons. Baldwin, bright scarlet, large, good branching habit; and Empress of Germany, white, tinged with rose, good habit, and free-blooming. The pink variety of Souvenir de la Malmaison is very tall-growing and flowers in the spring only, consequently is not perpetual flowering. The colour, however, is very pleasing, and the blooms are not much given to bursting. Mrs. George Hawtreys, a rich yellow variety, is another shy-blooming sort, and partakes more of the character of a border variety. Duke of Wellington, bright purple, has not grown well, but it will be given another trial from our own cuttings and which we prefer to small rooted plants as frequently supplied by the trade.—W. IGGULDEN.

TURNIPS ALL THE YEAR ROUND.

IN supplying a kitchen with vegetables all the year round there is nothing more constantly in demand than Turnips, and those who wish to please the cook and their employers should bear this in mind. A great quantity is rarely wanted at one time, but from half a dozen to twenty roots are about the daily requirements for an ordinary kitchen. From this it will be understood that to grow one or two large quarters of Turnips in the year would not be the best way of securing a regular

supply, as Turnips, like most other vegetables, soon become useless when they reach maturity.

The best way is to sow frequently, and above all to grow seasonable varieties. There would be no satisfaction or profit in growing an autumn Turnip in spring as a first crop, a winter one in summer, or only one variety for a supply at all seasons. Seedsmen who study the demands of their customers more than ever, generally classify the varieties as to season, and those wishing for suitable sorts should examine their lists before ordering, but to assist them in doing this at the present time I will name two or three which should be grown by all where a constant supply has to be maintained.

Two of the best early Turnips grown are the Early Milan and Early Munich. They are both purple tops, with flesh of snowy whiteness and of the finest flavour. Either of them, especially the Early Milan, if sown on the same day in March as the Early Snowball or Six Weeks, will be ready for use at least twelve days before the latter, and considering how much tender young Turnips are valued in spring, the fact is well worth remembering. Snowball and the American Strapleaf are good summer varieties. Veitch's Red Globe is one of the very best for autumn use, and Orange Jelly and Chirk Castle are unsurpassed for winter. With these varieties sown at proper intervals no one need have the slightest difficulty in having a supply of Turnips.

Soil to grow good Turnips should not be too heavy and only moderately rich. For the early spring crops the soil cannot be too light, but in summer it may be heavier and richer, as in this they remain tender and sweet in very dry weather. The latest sowings do very well in soil from which early Potatoes and Peas have been cleared. We have sown Turnip seed the last week in January, during February, and onwards, but we never had a really profitable crop from any seed sown before the first or second week in March, the plants lacked vigour and produced flowers before "bulbing." When the first seed is sown in March the Turnips will be ready early in May, and this is a very good time to have them. From March until the end of August seed should be sown every three or four weeks, and then the supply of fresh tender sweet roots will be constant. Our crop of Chirk Castle Turnips has just been lifted and stacked in the same way as farmers treat theirs, with a covering of Fern. There they will remain and keep fresh until new Turnips come again.—A KITCHEN GARDENER.

THE FORMATION AND KEEPING OF WALKS AND DRIVES.

THE first expense in making substantial roads on an estate is always heavy, even in localities where stone is plentiful and comparatively cheap. What, then, must it be where materials are scarce, or wanting altogether, as is sometimes the case? A few practical hints on this important subject may be acceptable to your readers. I now jot down a few thoughts suggested by my own experience, and I hope others may be induced to do the same, especially men of forty or fifty years' standing, as it is to such we must look to for information as to the durability of roads made in their younger days, the materials used, and the manner of using them.

Some men will make an equally durable road with half the material another may think necessary; so much depends on placing the stones on a properly prepared foundation. To make a good carriage drive on level well-drained land is a very simple matter. Having marked it out by placing pegs at regular distances, or notched it off with line and spade, excavate the soil to the depth of 9 inches or a foot deep at each side, but only from 3 to 6 inches in the centre, keeping it exactly the same shape as the road will be when finished. To secure good drainage—and this is especially necessary on heavy lands—dig a shallow drain about 9 inches below the bottom of your road, along both sides, and lay an ordinary 3-inch drain tile. Provide proper outlets for the water at convenient places, and where there is depression in the road gratings must be provided, so that surface water may not stand about the sides and soak into the road. Where these gratings are to be placed a square hole should be dug out about a foot below the drain, to be built up with brick, and the grating let into the top bricks. These are sometimes built too high. A new road, of course, always subsides a little, and if built up to the level of the fresh laid material it becomes useless when it has settled. Workmen should look more to the edge of the road, keeping the gratings 2 or 3 inches below the level of that. On very wet land it is advisable to keep such a road a little above the general level, and this may be done by excavating less soil and using

what is taken out to raise the sides, forming them similar to that shown at A fig. 58.

On such a foundation, 6 inches of granite, whinstone, or flint, broken to the size used in properly macadamising roads, will make a very fair road for such traffic as a carriage road on a gentleman's estate is subjected to. The first-named materials, or any others that equal them in hardness, are of course to be preferred; but flints if broken in the same way as the stone make a fair good road for light traffic. They should, however, never be used in a whole state. The rounded nodules, like coarse beach—also sometimes used—do not bind together, and have not the strength to resist a heavy pressure. The great point in making a road is to get the stones to fit into each other so as to form one mass and stand up as if it were a low arch of bricks. A few of the largest of the stones should be placed on the top of the drains at each side up to the level of the bottom, and then the whole of the surface should be covered with an equal thickness of stones. A thin layer of some suitable binding gravel should then be applied to the surface. If this can lie loose until it has a good soaking of rain, and is then rolled with a heavy roller, it will be all the better, as the top layer of stones will be less apt to get moved than they would if rolled at once. The gravel should not be applied too thickly—just enough to cover the stones when it is settled—and it should be of such a nature as to render the road, so long as it is kept up in the middle, as shown in our section, fig. 58, absolutely waterproof. I may say in passing, that in keeping it in this waterproof condition by never allowing it to become so worn in the centre by the horses' feet, or by the wheels as to give water the least lodgment, lies the secret of good keeping. But more of that anon.

In some localities it is found necessary to use a less hard material, such as freestone. This should not be broken so small, and a greater depth used, and also a greater depth of

Fig. 58.

gravel placed on the top. This will keep the direct wear off the freestone and provide for keeping the road even, as it cannot be expected to stand the same traffic as hard stone.

In other localities again we find stone of a slaty nature, such as is so plentiful in some parts of Scotland, where they utilise them in building "dry stone dikes" as fences. A very good road may be made of this stone by carting them on the road unbroken and setting them on edge, to the depth of from 6 to 12 inches just as they come, and afterwards breaking the rough points off with the hammer and working the pieces into the larger cavities so as to bring all up to a general level.

Road-making is generally prosecuted during winter, horse and hand labour being then generally less pressingly engaged on other work. I think, however, that it is a great mistake to do so during wet weather. It is especially desirable that the stones should be laid on a dry even surface, and this cannot be effected when it is wet, as the carts plough up the surface of the ground, and consequently there is sure to be some waste of material in the puddles that ensue, and the permanent lasting quality of the road is impaired.

The first steps in connection with making such a road over an undulating surface requires a little more thought and care than on a comparatively level surface. In the first place avoid sharp turns as far as possible. Let the curves be easy and graceful, and as far as possible correspond with the surrounding ground. Cutting through hills and filling up hollows after the manner of making a railway should never be tolerated, except in extreme cases, where the declivity of the ground is so sharp as to render it necessary. When a hollow is filled up ample time should be allowed for it to settle before the stones are placed upon it. In carrying a road across sloping ground some little care is necessary to strike on the right level, so that it will not have the appearance of navvy work about it. As a general rule level pegs may be inserted in the centre to the general level of the ground, and other pegs at each side made level with them. Excavate the soil from the top side and place it on the lower side to make it up to the level of the pegs. This gives a level space from which the soil has to be excavated for the stones in the usual way. A road in such a position should have a level piece of turf on each side, where possible, equal to half the width of the drive. To get this more soil will have to be taken from the high side and deposited on the lower side. The banks on each side should then be gradually sloped to

meet the general level of the surrounding ground as shown at A and B fig. 58. Very steep roads are very liable to be cut up by heavy rains. Gratings should be placed at shorter intervals, the roads kept well up in the centre, and a narrow channel at each side paved with round flints or some other material to prevent its being washed away.—R. INGLIS.

(To be continued.)

HARDY PLANTS IN FLOWER.

RANUNCULUS ANEMONOIDES.—This is Anemone-like to a great extent, having ternately pinnate leaves with numerous linear-oblong segments, rather glaucous, rising above which are the pretty capitula from 1 to 1½ inch across, with numerous white strap-shaped petals. It is indeed a gem among Buttercups, and but rarely met with under cultivation. Although not so fastidious, the plant from which these notes are taken is happily thriving in a damp semi-shaded part of the rock garden.

R. AMPLEXICAULIS.—This is just opening its first flowers, on stems about a foot high, prettily decorated with the stem-clasping leaves. The flowers are pure white, an inch or more across, each stem carrying several. It does remarkably well in a rich sandy soil, and it has not been disturbed till this spring for several years, consequently it had formed dense tufts. It appears not to thrive like this everywhere. It has been in cultivation in this country for a considerable time, for in Johnson's edition of Gerard it is figured and mentioned as being "a denizen of our gardens."

PRIMROSE "HARBINGER."—This is all that Mr. G. Abbey says of it. Like him, I am quite in love with it, and, doubtless, it will find a place in all gardens. It is one of the most useful and showy of the protean Primroses, and may be the progenitor of a sturdy race of white-flowered forms. Mr. Gilbert has sent out many good things, and, in my opinion, this will be one to gratify the million, and thus be ample reward for any raiser. Its large trusses of large white flowers are indeed very beautiful, and the freedom with which it grows in pots render it all the more valuable. It is one of the charming "hybrid Primroses" of which we can scarcely have too many in our gardens. Let every nook be made a pleasant garden with them, and many other pretty flowers which would be only too glad to associate with them.

THE "BLOOD ROOT" (*Sanguinaria canadensis*).—Another gem from the western hemisphere which is far too seldom seen, as it is most distinct and pretty, very hardy and easy to establish, especially in a damp position. It has been cultivated in this country since 1640. A good figure appeared in the "Botanical Magazine," t. 162, and a poor engraving is given in Parkinson's "Theatre of Plants," under the name of *Ranunculus virginianus albus*, or the "White Virginian Crowfoote," page 326; and on page 327 he thus describes it:—"The White Virginian Crowfoot shooteth forth from a reddish tuberous roote, with some small fibres thereto, three or foure somewhat large broad, whitish-green leaves, upon longe foote stalkes, rent or torne on the edges for the most part, along which riseth up a slender naked round stalke, 5 or 6 inches high, bearing one white flower at the toppe, made of tenne, or of twelve small narrow and pointed leaves, with a few yellowish threds in the middle set about a green umbone, which in time groweth to be a long slender pod wherein is contained round whitish seede." Truly a clear and minute description. It appears that Parkinson was the first to describe the plant in this country, for he says lower down the same page, "it hath not been set forth by any before."

DAFFODILS.—These flowers are now charming. The common Daffodil, *N. Pseudo-Narcissus*, is about the only *bonâ fide* species in the trumpet section, varying considerably, of course, but from one form to another there is every intermediate step which connects the whole. Look at *minimus* as the tiniest, and *lorifolius* Emperor or princeps as the largest, and cannot every gradation be traced? How difficult to find substantial points of distinction. In my opinion this is a chain in which there are no "missing links." This day I have examined two forms of *minimus*, one with a short perianth tube, the other lengthened, minor, three or four forms of *nanus*, *lobularis*, and *Pseudo-Narcissus*; and after several efforts to find for these true distinguishing features other than that of a slight difference in size and colour, I gave it up as hopeless. *N. spurius* is a large-flowered variety, very early, close upon princeps, but the latter is not yet in bloom. *N. moschatus* and *cernuus* are both in good order; the former is the earlier and much more robust, thriving well year after year, whereas *cernuus* frequently fails. *N. moschatus* I find increases freely, and has a shorter broader tube than *cernuus*. The double form of the *N. Pseudo-Narcissus* is extremely pretty. In a batch of collected bulbs of this species I have selected some double and semi-double flowers, which seem an evident passage from the single to the duplex form, and this fact gives one another new locality for the double

variety. *Telemonius* fl. pl. is perhaps the best known of all the double Daffodils. Mr. Wolley Dod has what he considers the single *Telemonius*, which is large and distinct from any I have seen. The Tenby Daffodil, *N. obvallaris*, is nearly self-coloured, but the perianth divisions are rather paler than the cup. I recently saw a flower of *N. obvallaris* major which was not much larger than the type, but the perianth segments were spreading at right angles to the trumpet, and rather broader than the species. It was collected in the Pyrenees, and I fancy Mr. Burbidge is responsible for the name.

BULBOCODIUM VERNUM.—This is a pretty little bulbous plant, but pink Colchicum-like flowers preceding the leaves; a tuft of it looks very effective in the woodland or at the foot of the rockery. Originally introduced from Spain about 1629, it was well known to Parkinson, who minutely describes it in his "Garden of Pleasant Flowers" under the name of the "Meadow Saffron of the Spring," but he makes no mention of the variegated-leaved variety which we now have, the leaves being margined with white. I find no mention of this in the old authors. Sweet does not note it as far as I have seen.

MUSCARI MOSCHATUM MAJOR OR FLAVUM.—This is a decided improvement upon the pale-coloured typical form—i.e., if it may be regarded as a variety of *M. moschatum* at all, and if any of the Grape Hyacinths are distinct I am inclined to think this is, and the name *macrocarpum* given to it in Sweet's "British Flower Garden," t. 210, should, I think, be retained rather than *M. moschatum* major, under which it is now distributed from continental centres. Certainly it favours *N. moschatum* more than any other species I know, but the perianth is much larger, decidedly ventricose, and not fluted, while the colour is a long way ahead. The first flowers to open are yellowish, ultimately tinged with red, while the upper ones are violet and in striking contrast with the others, and this gives the plant a very distinctive appearance. It is rather slow to increase by bulb offsets. Last year, however, I saved a batch of seed, and the seedlings are coming on well. It will be only by this means that it will become anything like plentiful in our gardens. Sweet says the figure referred to was taken at Messrs. Whitley & Co.'s nursery at Fulham, who received it as long back as the year 1812 from Constantinople, from whence it was sent by Lady Liston, and it is said to be one of the principal flowers with which the Turkish females continue to correspond in secret with their lovers.

M. ATLANTICUM.—One of the most handsome of the blue-flowered Grape Hyacinths, and second only in this respect to the rarer *M. armeniacum*. The peduncles are about 6 inches high, the floriferous portion 2 inches long, thickly covered with flowers. Perianth three lines long, cylindrical, slightly bulged in the middle, with a large open mouth and slightly spreading white rounded divisions, the tube being deep caerulean blue. It increases freely, and flowers equally free, so that very quickly a good tuft is formed, and a pretty feature added to the bulb garden. I am referring to its behaviour in a rich sandy soil with a good drainage. I am rather doubtful if it thrives so happily in a damp cold position or in clayey soil.

ANEMONE PATENS.—A large form of *A. Pulsatilla* of European hills, coming to us from the mountain ranges of north-west America. It grows about a foot high, the flower heads 3 inches or more across (one I measured this morning was rather over 4 inches), the sepals of a rich violet-purple colour and stout, surrounded by foliaceous silky bracts. The peduncle is also very silky, as well as the leaves, which are larger than those of the ordinary Pasqueflower, the segments broader and stouter. I cannot find that it extends as far west as California, but there is a species found there which is very closely related to this, if indeed it is not identical, or at most but a slender variety.—T. C.

A LECTURE ON THE NARCISSUS.

[Delivered before the Royal Horticultural Society at South Kensington, April 1st, 1884, by F. W. Burbidge, F.L.S., Curator, Trinity College Botanical Gardens, Dublin, and formerly of the Royal Gardens and Herbarium, Kew.]

INTRODUCTION.

HAVING been years ago (1868) a student in your then extensive and beautiful gardens at Chiswick, it gives me all the more pleasure to read a short paper here to-day. My subject is the Narcissus, or "Flower of March," the Daffodil that "comes before the swallow dares." Tennyson seems undecided whether to make the Daffodil belong to blustering March or to showery April. We all remember his "Roaring Moon of Daffodils," but in a still prettier passage he sings of

"A rosy blonde, and in a college gown,
That clad her like an April Daffodilly."

Pleasant as is my duty, yet when I look around me here I feel that it is presumptuous indeed on my part to speak before you on these flowers beautiful, since I must needs do so in the presence of those who really know far more of these fair "Lilies of Lententide" than I can hope to tell to you in half an hour.

Around us here to-day is, without a doubt, by far the finest collection of Narcissus blossoms ever brought together in one place. Thanks to the

energy of the honorary and active officers of your Society; thanks also many and sincere to the liberality of amateurs, as also to the enterprise of trade cultivators, we have here at our feet to-day a "field of the cloth of gold" even more brilliant than that one in particular which the old chroniclers have described so well; and the result of this gathering is a focussing, as it were, of all the golden beauty which Daffodil cups may contain. Speaking of Daffodil colour reminds me that this is by no means an ordinary flower show—no prizes are offered to-day, unless indeed it be that "crown of wild Olive" which the Greeks prized more than gold. We have here to-day an exhibition of flowers which have come to us for very love, and not for the sake of money prizes—an exhibition which proves that devotion to Flora as a queen among us is as yet a living truth, and that among or around the hearts of all true gardeners there is woven "a thread of twisted gold." But our time is limited, and I shall not further trouble you by way of introduction, but shall now with your permission proceed to the history of the Narcissus itself.

HISTORY.

It is generally believed that the earliest, or at least one of the earliest species of this genus to attract the attention of the wise men and poets of Greece first, and of Italy afterwards, was our garden favourite of to-day, *Narcissus poeticus*, hence, no doubt, its popular name of the "Poet's Narcissus." Both *Narcissus poeticus* and *Narcissus Tazetta* ("Little Cupped Italian" or "Polyanthus Narcissus") are mentioned by Dioscorides. Virgil also alludes to an "empurpled Narcissus," and although the exact plant is doubtful, yet it is by many believed that it was some form of *N. poeticus* which he had in view. Of far more moment to ourselves now is the great

Fig. 59.—Narcissus flower—1, scape; 2, spathe or bract; 3, ovary; 4, tube; 5, perianth segments; 6, crown or trunk (corona)

central fact that the Narcissi of our own gardens are as lovely here to-day as they were when the poets of Greece and Italy first sang their praises.

Nearly all early writers agree in treating this flower as an emblem of that beautiful boy whose name it bears. He is said to have slighted the nymph Echo in favour of his own shadow, and Nemesis changed him into this blossom as a punishment for his self-esteem. It is a deep-laid myth, and a pretty one as often told to us by the poets, and in one of the best of English translations we are informed the attendant nymphs in searching for the body of the ill-fated hero could see nothing but uprising stalks bearing golden blossoms—

"And looking for his corse they only found
A rising stalk with yellow blossoms crowned."

According to Shakespeare Proserpina let fall the Daffodil flowers she had been gathering when seized by Pluto, but, as Professor J. P. Mahaffy, F.T.C.D., informed me some time ago, the earliest accounts of this myth tell us a little too much, the flowers being therein spoken of as "Black Narcissus," hence we must believe, or at least suppose, that some other flower was originally intended. It may have been some Fritillary which had pleased the fair girl, since even at so late a date as 1629 we find John Parkinson in his "Paradisus" alluding to Fritillarias as "Chequered Daffodils." No doubt like Lily, Rose, and Violet, the name Daffodil or Narcissus had a much wider meaning and application in olden times than we give them to-day. For example, the Rev. H. N. Ellacombe in his "Plant Lore of Shakespeare" (p. 57), tells us that the "Rose of Sharon" was the large yellow Narcissus common in Palestine and the East generally, of which Mahomet said, "He that has two cakes of bread let him sell one of them for some flowers of the Narcissus, for bread is food for the body, but Narcissus is the food of the soul."

The name Daffodil is said by some scholars to be "simply the old English word 'affodyle,' which signifies that which cometh early." Dr. Prior, however, who is no mean authority, looks upon it as a corruption of the Latin *Asphodelus*, and thus it may be identical with the *Asphodel*. He further tells us that the name Daffodil "was subsequently confused with that of another flower, the so-called Sapharoun," or "Saffron Lily." By alliteration the "Sapharoun Lily," on becoming blended with "Affodilly," became by a

ort of mutual compromise "Daffadowndilly," in which form it is used by Spencer in the lines, "Thy summer proude with Daffadillies dight," and "Strowe the green round with Daffadowndillies." Daffodil and Asphodel have, however, long been distinct enough in popular parlance; but there was at one time a danger of confounding them, since Markham, in his "English House Wife" (1637), says, "You must be careful that you take not Daffodil for Asphodel." Among the many local or country names for the Daffodil the most common now-a-days are Lent-Bellflower, Lenten Rose, "Lent Lilies," "Trumpets," "Trumpet flowers," and "Chalice flowers." Culpepper calls it Lide Lily, because it flowereth in March, which month in some counties is called "Lide," "Lide" itself, like "Lent," being an equivalent for the spring season. Popular names have fit uses, but unless very carefully applied they are apt to lead us astray sometimes, and so we must always remember that the popular name Daffodil in all its forms (excepting the "Hooped Petticoat" or "Rush-leaved" Daffodil, which is different) is applied only to the varieties of that very variable native plant, *Narcissus pseudo-Narcissus*, the wild Daffodil of our meadows and northern Europe, or the False or Spurious Daffodil of Parkinson, who so called it doubtless to distinguish it from the other flat-leaved or true *Narcissi*, of which *Narcissus poeticus* and *Narcissus Tazetta* may be taken as good types.

POPULAR NAMES OF THE SECTIONS.—All varieties of *Narcissus Pseudo-Narcissus*, then, whether native or foreign, may be called "Flat-leaved" or "Trumpet Daffodils."

All forms of *Narcissus Bulbocodium* (the *Corbularias* of some gardens) may be called "Hooped Petticoat" or "Rush-leaved Daffodils."

"Jonquil" is another popular name, belonging by right to *Narcissus jonquilla*, but it may be applied to any true *Narcissus* having narrow bright green or rush-like leaves.

The "Poet's *Narcissi*" are all those which have pure white perianth segments and a distinct red or purple rim to the shallow yellowish corona or crown.

"*Polyanthus Narcissi*" are, properly speaking, all forms of *Narcissus Tazetta*.

The "Peerless *Narcissi*" are all those of the *N. incomparabilis* type in the genus, and the "Primrose Peerless" is *Narcissus biflorus*.

Hence these popular names, which confuse us so much when loosely applied, if used rightly and carefully serve to distinguish for us the different well-marked sections of this beautiful genus.

STRUCTURE OF THE NARCISSI.

We shall now turn to the structure and botany of the *Narcissus* as it is known to us to-day. The species of *Narcissus* (for even Daffodils are, strictly speaking, *Narcissi*, although only the large-trunked *Narcissi* are Daffodils) form a genus of bulbous plants belonging to the natural order or group *Amaryllidaceae*, of which the *Amaryllis* is the type. But our *Narcissi* differ from *Amaryllis* proper in having a crown or corona, and thus they represent for us here in Europe, not the *Amaryllis* itself, but the *Eucharis* and *Hymenocallis* of the new world. At the same time the structure and origin of the crown seems different. In *Eucharis* the corona is formed by the cohesion of the flattened filaments of the anthers, which themselves are joined to and protrude beyond the crown they form. In *Narcissus*, however, the corona appears to be a prolongation of the tubular portion of the flower. A *Narcissus* flower when examined is found to possess an inferior ovary situated at the base of a cylindrical or obconical tube. From varying localities along this tube spring six perianth divisions (in two series), and beyond these a cup or crown is prolonged as shown in fig. 59.

DAFFODILS versus NARCISSI.—Now we find among the *Narcissi* generally two well-marked and distinct variations in their flowers. In the Daffodils, for example, the six stamens are of equal length, and have the same point of insertion low down near the obconical tube as here shown (fig. 60):—

Fig. 60.—Daffodil.

When a flower of the true or "Poet's *Narcissus*" is examined, however, we find some marked differences, as shown in the diagram (fig. 61).

It will be observed that the tube is here very much longer and quite cylindrical, and when we make a section of the flower we find the six stamens are divided into two sets of three each, and that each set has its own locality or point of insertion—three near the mouth and the other three much further down, midway twixt crown and ovary. I have not time to go into minute details; but I need scarcely say that there are good reasons for these structural variations. They are especially fitted for (owe their origin, it may be), to insect fertilisation; and, as we shall soon find, these two distinct species are not unfrequently cross-fertilised in a wild state, and this has happened much more frequently in our gardens, or perhaps it may be in gardens their progeny has been more carefully preserved. Before I leave this part of my subject I wish to point out that nearly all the variations in

form of which a *Narcissus* flower is capable are owing to the sliding, as it were, of the whorl of perianth segments along the tube of the flower. Thus we find the length of the cup or crown and the length of the tube always, or nearly always, vary in inverse proportion, just as I have shown them to do in the sketch (fig. 62).

It is well to get the essential differences of these two species well fixed in

Fig. 61.—Poet's *Narcissus*.

our minds, as we thus get a clear light in which to see the part each species has borne in the production of garden hybrids and seedlings.

I ought to point out here that some superficial distinctions are produced by the manner and degree of expansion usual to the perianth divisions. In the "Hooped Petticoat" (*Narcissus Bulbocodium*), for example, the perianth divisions are narrow and inconspicuous, lying as they do in the same plane with the coronal margins. In the "Common Daffodil" the perianth lobes are broader and more expanded. In *N. incomparabilis* and in *N. poeticus* they are expanded at right angles to the tube and so become star-like; so also in the "Little Cupped Italian" or *Narcissus Tazetta* group, while in the case of this "bonnie" gem *Narcissus triandrus* we get a very distinct Cyclamen-like blossom, seeing that the perianth lobes are sharply reflexed or turned back, so that they be parallel with the pendant flower tube.

THE COLOUR OF NARCISSI.—In colour the *Narcissi* are not so variable as many other bulbous flowers. We get all shades of yellow and of white in the perianth. One species, *N. viridiflorus*, known to Parkinson, and recently re-introduced by Mr. George Maw, has greenish blossoms. Among the *N. incomparabilis* varieties we find cups richly tinted with orange-red; so also in some forms of *N. Tazetta*, while *N. poeticus* has a red or purple rim to the crown.

Fig. 62.—Daffodil with long crown and short tube, *Narcissus* with short crown and long tube.

"Everybody knows that the common Daffodil has an extinguisher-shaped deep yellow corona an inch or more in length, while the cup of the "Poet's *Narcissus*" is flat and shallow, yellow also, but having a dark reddish-purple rim around its margin. Now, in the hybrid *N. incomparabilis* and many of its seedling forms we find the outer edge of the cup suffused with reddish-orange, which is just the tint obtainable by mixing deep yellow and reddish-purple on the palette."—(*Burb. "Cult. Plants," 1875, p. 125.*)

THE SPECIES OF NARCISSI.—We must now pass in review the species of the genus, and I shall be glad if you will allow me to refer briefly to their classification afterward.

NOMENCLATURE OF THE NARCISSI.—We have in all about twenty species of *Narcissus* which are known to exist in a wild state.

LIST OF THE SPECIES OF NARCISSI, SHOWING DISTRIBUTION.

Species.	Native Countries.
1, <i>N. Pseudo-Narcissus</i>	Sweden, England, Portugal, Spain, Italy, Transylvania.
2, <i>N. Bulbocodium</i>	Spain, Portugal, France S.W. to Bordeaux, N. Africa.
3, <i>N. incomparabilis</i>	Spain, S.W. France, Tyrol.
4, <i>N. Maeleaii</i>	Not wild.
5, <i>N. dubius</i>	S. France, (Toulon, Marseilles, Avignon, Nice).
6, <i>N. poculiformis</i>	(montanus) not wild.
7, <i>N. odorus</i>	Spain, S. France, Italy, Dalmatia.
8, <i>N. juncifolius</i>	Spain, and S. France.
9, <i>N. triandrus</i>	Spain.
10, <i>N. calathinus</i>	Isle of Glenans, Brittany.
11, <i>N. Tazetta</i>	S. Europe, Cashmere, N. India, China, Japan.
12, <i>N. pachybolbus</i>	Algeria (? <i>N. Tazetta</i> var.).
13, <i>N. biflorus</i>	France, Switzerland, Italy, Tyrol.
14, <i>N. poeticus</i>	S. Europe, France to Greece.
15, <i>N. Broussonetii</i>	Mogadore (Africa).
16, <i>N. canariensis</i>	Canary Islands.

Species.	Native Country.
17, N. intermedius	Spain, S. France, Balearic Islands.
18, N. gracilis	Not wild.
19, N. Jonquilla	Spain, S. France, Italy to Dalmatia.
20, N. jonquilloides(Willkom Fl. Hisp.) Spain.
21, N. viridiflorus	Spain and Barbary.
22, N. elegans	Italy, Sicily, Algiers.
23, N. serotinus	Spain, S. Europe, Barbary States, Greece and Palestine.

DOUBTFUL SPECIES OF NARCISSUS.—I may here mention that among generally acknowledged species there are two or three which have never been found wild. These are N. Macleaii, N. poculiformis (montanus), and N. gracilis. It is questionable if these are really species, my own opinion being that they are old and well-marked garden hybrids or seedlings. N. pachybolbus and N. canariensis should, I think, be considered as outlying geographical forms of N. Tazetta. N. jonquilloides of the "Flora Hispanica" (Willkom) I have not seen alive, but in the plate it resembles N. intermedius. N. calathinus must now be referred to N. triandrus.

Others, again, which really do exist wild without a doubt, have also had their exact counterparts produced in gardens. Thus, on the authority of Dean Herbert and others, N. incomparabilis and N. odorus, both well known as wild in Southern Europe, have been produced in gardens by hybridisation.

EARLY CULTURE OF NARCISSUS.—Most of the species of Narcissus were known to the early English gardeners, more particularly to John Parkinson, who figures and describes ninety-six species and varieties in the year 1629.

GEOGRAPHY OF THE NARCISSUS.—Nearly all these kinds are found wild in Europe. Spain and the south of France seem to be the focus of the genus, but a few are found in northern Africa.

N. Tazetta is most ubiquitous, growing all over southern Europe and northern Africa, and then going off at a tangent through Persia, Cashmere, and India as far east as China and Japan.

CLASSIFICATION OF THE NARCISSUS.—Parkinson seems to have been the first to attempt any classification, and he is very particular that we should distinguish Daffodils from Narcissus proper, and is equally careful lest we should confound the flat-leaved with the rush-leaved kinds. At a more recent date Salisbury, Haworth, and Herbert all worked among these flowers, but their methods of classification, although most interesting to garden students, are now botanically obsolete. We are indebted to Mr. J. G. Baker of Kew for a clear and useful system of grouping, published in 1869, and it is this system, with a few modifications, I shall bring before you to-day.

Mr. Baker's plan depends on the relative length which naturally exists between the perianth segments as contrasted with the cup or corona, and I have divided these three main divisions into flat-leaved and rush-leaved groups.

The three main divisions as characterised by the varying size of their cups or crowns may be thus popularised :—

- LARGE-TRUNKED.
GROUP I. (MAGNICORONATE) or "COFFEE-CUP" SECTION.
- MEDIUM-CUPPED.
GROUP II. (MEDIOCORONATE), or "TEA-CUP" SECTION.
- SMALL-CROWNED.
GROUP III. (PARVICORONATE), or "TEA-SAUCE" SECTION.

CLASSIFICATION OF THE GENUS NARCISSUS.

GROUP I. Magnicoronatæ. Crown as long, or longer than the perianth divisions.	GROUP II. Mediocoronatæ. Crown half or rarely three-quarters as long as the perianth divisions.	GROUP III. Parvicoronatæ. Crown less than half as long as the perianth divisions.
<div>TRUMPET DAFFODIL. a. Flat-leaved. 1. N. Pseudo-Narcissus vars.</div> <div>HOOPED-PETTICOAT DAFFODIL. b. Rush-leaved. 2. N. Bulbocodium vars.</div>	<div>MEDIUM-CUPPED NARCISSUS. a. Flat-leaved. 3. N. incomparabilis 4. N. Macleaii 5. N. dubius 6. N. poculiformis</div> <div>b. Rush-leaved. 7. N. odorus 8. N. juncifolius 9. N. triandrus 10. N. calathinus</div>	<div>SMALL-CROWNED NARCISSUS. a. Flat-leaved. 11. N. Tazetta 12. N. pachybolbus 13. N. biflorus 14. N. poeticus 15. N. Broussonetii 16. N. canariensis</div> <div>b. Rush-leaved. 17. N. intermedius 18. N. gracilis 19. N. Jonquilla 20. N. jonquilloides 21. N. viridiflorus 22. N. elegans 23. N. serotinus</div>
<div>a. Flat-leaved. 1. N. pseudo-Narcissus.—The type of this species is the common Daffodil of English meadows and orchards, and of this type there are innumerable forms, ranging from the tiny N. minimus up to N. maximus, which is the tallest and largest of its race. All the varieties have flat glaucous leaves.</div> <div>b. Rush-leaved. 2. N. Bulbocodium.—The type of this species is N. Bulbocodium, the "Rush-leaved" or "Hooped Petticoat" Daffodil of Southern Europe. There are many varieties, all easily recognised by the expanded crinoline-like corona, narrow perianth segments, declinate stamens, and green rush-like leaves.</div>	<div>a. Flat-leaved. 3. N. incomparabilis.—1-flowered; leaf half an inch broad, glaucous. 4. N. Macleaii.—1-2-flowered; leaves broad, greenish; crown bright yellow, three-quarters as long as the spreading white perianth segments. (?) Hybrid. 5. N. dubius.—Many-flowered, with flattish glaucous leaves; perianth segments 3-5 lines long, cup 3 lines deep. 6. N. poculiformis.—1-2-flowered, all white; crown half as long as the perianth divisions; flower "dog-eared," but 3-4 inches in diameter.</div> <div>b. Rush-leaved. 7. N. odorus (Campernelle Jonquil).—All yellow, 2-5-flowered, with bright green Rush-like leaves. 8. N. juncifolius.—1-5-flowered, much smaller than N. odorus, with a flattish corona. 9. N. triandrus.—1-5-flowered, perianth divisions reflexed like a Cyclamen flower. 10. N. calathinus.—1-2-flowered, with reflexed segments like the last; perhaps only a geographical form of it, having larger flowers.</div>	<div>a. Flat-leaved. 11. N. Tazetta.—Many-flowered, with flat glaucous leaves; very variable. *12. N. pachybolbus. 13. N. biflorus.—1-3-flowered; flowers like N. poeticus; creamy white, cup pure yellow. 14. N. poeticus.—1-flowered; white, with a purple or red edge to the crown. 15. N. Broussonetii.—Crown nearly suppressed. *16. N. canariensis.</div> <div>b. Rush-leaved. 17. N. intermedius.—A many-flowered yellow N. Tazetta with rush leaves. 18. N. gracilis.—1-2-flowered; flowers pale yellow, as large as N. poeticus. 19. N. jonquilla.—Many-flowered; flowers deep yellow; very fragrant. 20. N. jonquilloides.—(Willkom Fl. Hisp.).</div> <div>c. Autumn-flowering. 21. N. viridiflorus.—Many-flowered; perianth greenish. 22. N. elegans.—1-3-flowered; pure white. 23. N. serotinus.—Flowers after the leaves very like the last, but with broader perianth segments.</div>

THE HYBRID AND SEEDLING NARCISSUS.

When we come to speak of Narcissus hybrids it is a matter of regret that the workers in this fertile field have left us scarcely any data or notes of how their numerous seedling and hybrid forms were produced. Dean Herbert (in Jour. R. H. S., vol. ii., p. 1) has told us more than anyone; and the late Mr. W. Backhouse of St. John's, Walsingham (who raised the "Empress" and "Emperor" Daffodils), contributed an interesting paper to the Gard. Chron. for June 10th, 1865. The late Mr. Leeds of Longford Bridge, Manchester, who raised more new kinds than anyone else, gave us no information whatever, nor did the late John Horsefield, the Lancashire weaver, who raised the "Bicolor Horsefieldii Daffodil," decidedly one of the most robust and beautiful of its race. The late Mr. Nelson, of Aldborough Rectory near Norwich, raised a few varieties of especial merit, notably the noble sulphur Daffodil named "Gertrude Jekyll," and a white form of the dwarf Daffodil (N. nanus). Mr. Nelson kindly told me by letter only a few days before his death that cross-fertilisation was not resorted to. So Mynheer Simon de Graaff of Leiden informs me that his fine new kinds are seedlings or wind-fertilised hybrids. These remarks corroborate what Mr. Backhouse wrote in the Gardeners' Chronicle twenty years ago (June 10th, 1865), when, speaking of artificial crosses between the "Daffodil" and the "Poet's Narcissus," he says, "Seeds I have sown from plants not artificially impregnated produce the same result, some showing the Daffodil and others the N. poeticus type." The moral here would seem to be, Raise seedlings—hybrids if you can—but raise seedlings."

Here is a list of all known type hybrids so far as we at present know them.

HYBRID NARCISSUS.

PARENTS.	HYBRIDS.
N. Pseudo-Narcissus × N. poeticus	= × N. incomparabilis.

DERIVATIVE HYBRIDS OF NARCISSUS.

Some of these hybrids have again yielded seedlings, so that the variations now observable are of the most divergent and perplexing kind; so much so indeed that some have complained that there is too much sameness among the newer kinds of Narcissus. This much is true of Roses or Auriculas, indeed of nearly all garden flowers, and after all it is easy to use one's eyes on a day like this, noting the most beautiful from one's own standpoint, and resolutely avoiding those which do not please our taste. To my mind the delicate chromatic scale—the subtleties of form and of colour these new seedlings afford us—are most beautiful, and a garden tastefully planted with

them would afford its owner beauty of a most satisfying kind, even if it did not prove a "joy for ever."

POETRY OF THE NARCISSUS.

Of this I shall say nothing more, since in the first place I am sure it is in your hearts, or at least you may find it in your libraries. But I have a few words to say in conclusion on the cultivation of these beautiful flowers.

CULTURE.

The culture of all the Daffodils and of nearly all the Narcissus is not difficult. Most of them are robust enough to increase in beauty from year to year if planted at the proper season in well-tilled soil. Some of the dwarf and tender species, as *N. triandrus*, *N. juncifolius*, *N. Bulbocodium* (especially the paler forms), *N. viridiflorus*, *N. elegans*, and *N. serotinus*, succeed best in pots in a cool house or frame. The white race of Daffodils also do best on a warm sunny border, but the yellow and bicolor Daffodils, and nearly all the hybrid kinds, will luxuriate in the open air border almost anywhere. The proper time to transplant your Narcissus generally is in June, July, or August. They may be dug up as soon as the foliage has withered away, and if replanted immediately in good well-drained soil they do not suffer much, if any, by removal. It is a good plan to mulch well with rotten manure just before flowering time; and if you want very fine fresh flowers for show or decorative uses cut them whilst they are in the bud stage, and place them in water indoors to expand.

If you post flowers to your friends pack them in the bud stage. You can thus send many buds, which will each and all open fresh and fair if placed in water immediately on their arrival. It only remains for me, Mr. Chairman, and ladies and gentlemen, to thank you for the kind attention you have given me.

AN INTERNATIONAL EXHIBITION is announced to be opened at Antwerp in May, 1885, which will include contributions of plants and other horticultural productions, besides the ordinary commercial exhibits and examples of art. It is under the patronage of King Leopold.

— THE charming little rock plant, *PRIMULA FLORIBUNDA*, is no much known at present, but well deserves attention; for though dwarf in habit and its flowers very diminutive, their colour is such a bright shade of yellow, they are so numerous, and are produced in succession over so long a period, that it is certain to become a general favourite. It is readily increased by seeds, and is attractive when grown in pots for a cool house.

— THE WIMBLEDON AND DISTRICT HORTICULTURAL SOCIETY will hold their twelfth annual Exhibition in the grounds of Wimbledon House, on Wednesday, July 2nd. A large number of special prizes are offered by local supporters of the Society, in addition to those provided in the schedule, which enumerates eighty-five classes.

— *AJESA REFENS PURPUREA*.—An advertisement in a contemporary has been brought to our notice in which a plant for carpet bedding is described under the above remarkable name. It is quite new to us, and we should be glad to have further information about it. Is it possible that *Ajuga reptans* is the plant intended?

— THE CROYDON HORTICULTURAL SOCIETY'S SHOWS for the present year are announced for June 25th and November 11th and 12th. The former to be held in the grounds of Wellesley House, and the latter in the small Public Hall, Croydon. At both the classes are numerous and the prizes of good value, especially in the open classes.

— A CORRESPONDENT writes:—"In the report upon LIVERPOOL SPRING SHOW, page 245 of your last issue, a mistake occurs as to the number of collections of herbaceous and bulbous plants staged. It is there stated that 'only two collections were staged,' whereas there were three. Amongst the plants credited to the Chester collection were *Primula Sieboldi*, *P. rosea*, *Narcissus Trumpet major*, and *Iris Beauty*, none of which belonged to that collection; and while *N. Trumpet major* is adopted as a variety of *N. odoratus*, there is still room for great improvement."

— THE BATH FLORAL FETE COMMITTEE announce the following exhibitions for the present year:—A spring show, May 14th; Rose show, July 3rd; autumn show, September 3rd and 4th; and Chrysanthemum show, November 12th and 13th. Liberal prizes are offered in all the leading classes at each exhibition; plants, flowers, fruit, and vegetables being duly provided for.

— MESSRS. S. MAHOOD & SON, Putney, send us a collection of SPRING FLOWERS, including pretty specimens of *Chionodoxa Luciliae*, with flowers large and bright blue; *Anemone Robinsoniana*, early, flowers of good colour; *Muscari pallens*, really a pale blue variety of *M. botryoides*; the Nodding Star of Bethlehem, *Ornithogalum nutans*; *Triteleia uniflora* and *lilacina*, white and lilac; the Caucasian Leopard's Bane, *Doronicum caucasicum*, large and bright yellow; *Anemone fulgens*, single and double, most brilliant and handsome; the Spring Snowflake, *Lencium vernum*; *Iris reticulata*, and *Fumaria officinalis*.

— THE NORTHAMPTONSHIRE CHRYSANTHEMUM SOCIETY'S THIRTEENTH ANNUAL SHOW will be held in the Corn Exchange, Northampton, on November 19th and 20th of the present year, when prizes ranging in value from four guineas to one shilling will be offered in sixty-six classes for Chrysanthemum blooms, specimen plants, and vegetables.

— GARDENING APPOINTMENT.—Mr. John Wyke, formerly gardener to J. P. Kidston, Esq., Nym Park, Barnet, Herts, has been appointed gardener to Captain Alcock, Henley Grove, Westbury-on-Trym, near Bristol.

— WE have received the schedule of prizes of the CATERHAM HORTICULTURAL SOCIETY, the sixth annual show of which is to be held on July 23rd. The report states that the Society has two objects—the improvement of the gardeners of the district and the development of practical gardening among cottagers. Both these are good objects, and we wish the Society success.

— MR. W. J. CARVILLE, of Lewes, instances as evidence of the EARLINESS OF THE SEASON the circumstance of his cutting a bunch of *Asparagus* from the open ground on April 1st.

— THE largest producers of TOBACCO are the American States of Kentucky, Virginia, North Carolina, and Tennessee. The production for 1882 was 513,077,588 lbs., grown on 671,522 acres, or about 1000 square miles, and valued at 43,189,951 dollars. The average value was 64.32 dollars per acre. This is more profitable than Wheat or corn-growing would be in the same districts. In 1883 America exported Tobacco to the value of 22,095,229 dollars, and imported to the value of 11,775,596 dollars, or over 50 per cent. of our exports.

— THE value of COW MANURE AS A STIMULANT FOR PLANTS has been long known in gardens, but never until recent years has it been so largely and generally employed for plants that have previously been considered independent of such assistance. A man who some years ago might have suggested giving it to Orchids or *Nepenthes* would have been almost regarded as insane, yet some of the best-grown Pitcher-plants that we have seen are greatly aided by cow manure administered in a mild diluted form, while most of the stronger-growing Orchids, such as *Dendrobies*, are similarly treated with proportionate advantage. Water Lilies are much benefited by a liberal admixture of this manure with the compost, and we have heard of one experienced cultivator who is very successful with the queen of Water Lilies—the *Victoria regia*—employing one cartload of cow manure to three of loam as soil, this apparently large proportion resulting in foliage of astonishing vigour and large flowers.

— IN the Palm house at Kew a fine specimen of *COFFEA ARABICA* is now fruiting well, and has a remarkably handsome appearance. The tree is 12 feet high, furnished with branches to near the base, and these are thickly studded with the bright crimson oval fruits, the total number being about 400. Very rarely is a Coffee plant seen in such good condition in England, and its horticultural value cannot be overestimated when fruiting so freely as this one is.

— THE OLD LILY HOUSE in the same establishment is being reorganised, and it is now disconnected from the Palm house in the heating arrangements. A great difficulty has long been experienced in insuring a full command of heat for the smaller house owing to the distance the pipes had to be taken underground, and this was particularly felt when the *Victoria regia* was grown there. Now a new boiler has been placed at the back, and it is intended to keep the house attractive throughout the year, instead of having it closed for several months, as has hitherto been the custom. *Nymphæas* will receive especial attention, and the roof will be clothed with climbing plants of rich *Ipomæas*.

— NEW GARDENING BOOK.—We hear that, under the title of "The Illustrated Dictionary of Gardening," an elaborate work on gardening is being issued in serial form from 170, Strand, London.

It is in the "popular and convenient form of a dictionary, and will give particulars of, and cultural directions for, all garden plants."

— INTERNATIONAL HEALTH EXHIBITION.—The great interest manifested in the Exhibition is shown by the fact that application has been made by British exhibitors alone for space five times as great as that actually at the disposal of the Executive Council. On the 15th of this month the first goods will be admitted. Information has recently been received that the French Government has appointed a Commission; and Italy—owing in a great measure to the individual exertions of a member of the Executive Council—will, it is hoped, take an active part. A portion of the Educational Section of the Exhibition will be located in the Central Institute of the City of London Technical Guilds, the handsome building in course of erection in the Exhibition Road, which has been kindly placed at the disposal of the Executive Council. The Royal Albert Hall with its musical attractions will now form an integral part of the Exhibition; and the Aquarium, a popular feature of the late Fisheries Exhibition, will continue as an important part of the Health Exhibition. In the Dress Section the most popular exhibit will probably prove to be a series which is being prepared, illustrative of English dress of all ranks of life, from the time of the Conquest to George IV. While the main objects of the Exhibition—which are to impart instruction on the principal sections of the undertaking—have received the fullest attention from the Executive Council, the amusement of the visitors has not been overlooked. The band of the Grenadier Guards, under the able conductorship of Mr. Dan Godfrey, will, as last year, perform each day; and, actuated by the success which attended the visit of the Thuringian Regimental Band to the Fisheries Exhibition, the Executive Council have taken such steps as may, it is hoped, lead to the visit of representative foreign military bands this summer. It is also intended that concerts shall from time to time be given in the Albert Hall. An International Congress on Education will be held, and conferences and lectures will conduce to the elucidation of the subjects of the Exhibition. It is also proposed to have a library and reading room in connection with the Exhibition, which will be open to all visitors, under proper regulations, while the Exhibition is open. The library will consist of books on various subjects comprised in the classification of the Exhibition, both English and foreign. Application has been addressed to foreign and colonial Governments, asking them for copies of reports and statistics on sanitary and educational matters, and a circular is being sent out to authors and publishers requesting them to contribute works of a similar character.

POTTING ORCHIDS.

MANY Orchids decline in health through negligence in potting not perhaps with those who make a special study of them, but in some gardens a very loose system of management is practised. Another system that is more general than supposed, is the removal of a portion of the surface compost and supplying fresh. This is very good when repotting is not needed, but is wrong when the plants are subjected to it annually, as if the cultivator were afraid to disturb his plants. Plants so treated cannot long be expected to remain healthy.

The "letting alone" principle is wrong, and gardeners had better not commence the culture of these plants if the time and attention required in potting cannot be devoted to them. Badly grown sickly specimens do more to discourage the extension of Orchid culture than any other cause. It must be understood that Orchids dislike decomposed material about their roots. If they are to do well they must have sweet compost about their roots, and in order to accomplish this the old material must be removed annually. Any system of potting on the same principle as that followed for Azaleas or Pelargoniums when they require a larger pot is unsuited for these plants, and cannot be too strongly condemned.

Many Orchids while growing require large supplies of water; in fact, *Aerides*, *Phalænopses*, *Vandas*, *Saccolabiums*, *Cypripediums*, *Odontoglossums*, *Cœlogynes*, *Masdevallias*, and others, need it in abundance all the year. Sphagnum moss will not remain in the pots and baskets of these plants in a fresh condition longer than one year, and after that space of time it should be removed. Peat will last longer, but this depends upon its quality. If only the fibre is used it will last for two years, but is then often much decomposed, and, where practicable, I advise annual removal.

In my notes on *Phalænopsis* I detailed how they should be

attended to, but we will consider *Aerides*, *Vandas*, and *Saccolabiums*, all of which will do well either in pots or in baskets. It is not necessary that the plants should be supplied with larger pots or baskets every year the potting has to be performed; they need not be taken out until they require a larger size, which may not at the least be earlier than two years. In the first instance the pots should be thoroughly clean, and then partly filled with drainage, to allow the plant being placed in position, but this matter depends upon the length of the stem and roots. If long, lumps of charcoal and crocks can be carefully laid amongst the roots to within 2 inches of the rim of the pots. In many instances the pots may be filled to this before the plants have to be placed in them. For these Orchids I prefer a mixture of charcoal and crocks. The material used for drainage should be so placed that when the compost is removed annually the small decomposed particles can be washed out through the bottom. After this the remaining portion of the pots should be filled with living sphagnum moss well elevated above the rim. Amongst this may be added a few lumps of charcoal and crocks. Sphagnum moss is better for these plants than a mixture of it and peat. This moss at the end of one year will be sufficiently decomposed for removal, and is readily picked out from amongst the roots without disturbing the plants. The crocks and charcoal intermixed with the moss can also be removed if no roots are clinging to them. After all has been removed, wash out the remaining small particles by pouring tepid water into the pot. This leaves the roots and drainage perfectly clean. The same process may be followed with plants in baskets, only they will not need more than one good layer of crocks or charcoal at the bottom.

Cypripediums appear to flourish even when the material in which they are growing is thoroughly decomposed. But it is not wise to allow them to get into this condition before the compost is renewed. All small or moderate-sized specimens are examined annually, and those in large pans turned out every second or third year. These plants are as difficult to repot without injury to their roots as the majority of Orchids, for they cling tenaciously to the sides of the pots or pans. There is no means of taking them out without breaking the pots and pans, and this we do without regret when they are not of a large size. To obviate this I have of late filled these pans with crocks and charcoal within an inch of the surface, and the plants are in consequence elevated higher than would be the case if a less quantity of drainage was employed. I hope by this system to remove the potting material annually instead of turning them out so frequently. For large plants I use one-third of peat fibre to two-thirds of living sphagnum moss. I prefer charcoal and crocks mixed with this, only the roots cling so freely and fast to them that they are dispensed with because they render the removal of the compost more difficult. Some varieties do well in loam, but from the quantity of water required I do not care to use it. If it is used it is laid near the surface so that it can be readily removed when the fibre is decomposed. I have applied cow manure in a dry state under the surfacing of moss, but prefer giving stimulants in the form of liquid manure while the plants are growing if required. Small bones are good for these plants, and I am informed that limestone chippings mixed with the compost is valuable for some species, including that distinct and beautiful variety *C. Spicerianum*.

From *Dendrobiums* the entire compost is not removed annually, only the surface being freshened; but every second year, where practicable, the whole is removed. This is rather a difficult operation when the plants are growing in baskets, for the roots of many species appear to fully occupy every particle of material when they are strong. With care a good portion can, however, be removed, and I have found free-growing *Dendrobies* not so much injured by a few roots being broken as is the case with many Orchids, but the fewer roots broken the better. These plants do well in either pots or baskets. When growing in pots two-thirds of peat fibre to one of moss, with lumps of charcoal freely intermixed, and a little coarse sand is used for the compost; but when growing in baskets the moss is allowed to predominate, and small crocks mixed with it in preference to the charcoal. When these plants require new or larger baskets, which they will do in two or three years, and this opportunity must be seized for washing and picking away the whole of the old material from the roots.

Cattleyas and *Lælias* are the most difficult Orchids to deal with in respect to potting, and they appear to suffer more than any other Orchids by the slightest injury to their roots. The peat and moss employed for these plants will last much longer in good condition, because they do not require so much water during the winter and spring months—in fact, in no period of their growth, as is the case with many Orchids. Imported

plants are best potted in crocks only until they are throwing out fresh roots, when peat and moss may be added. Established plants are only disturbed every second or third year, generally the former, and if larger pots are required a shift is given them, so as to keep if possible their roots in the compost and pots or pans, whichever may be used; the latter are preferable. The pots in which established plants have been growing must be broken, for the roots of the plants if healthy are sure to be found clinging to the sides. The portions of the pot to which the roots adhere should be placed into the new pots without being disturbed. The old peat and moss must be removed, and fresh worked most carefully amongst the roots without breaking them. There is a variety of opinions about the best time to repot these plants. I am no advocate for allowing them to commence making fresh roots before the operation is performed, the majority of our plants being potted just as they commence growth and before they form roots. I am not sure, however, where the watering is done carefully and judiciously, if this is not best done even before they commence growth. I have been subjecting a plant of *C. Mossiae* to this treatment, and it has flourished well. Three years ago when obtained it was just maturing a small-flowering pseudo-bulb. The flower was removed, and the following season a strong-flowering pseudo-bulb was made, and a stronger still the following season. Last spring the one produced two strong growths, each now carrying flowering sheaths. Two of the back eyes have started, and are likely to make strong pseudo-bulbs, so that the plant has now four leads, and until this season only in a 5-inch pot. I am testing this matter on a larger scale this year.

Oncidiums, *Masdevallias*, *Odontoglossums*, and others are repotted annually, removing every portion of the compost given them the previous year. For the last two mentioned scarcely too much moss can be used, for they appear to root more freely amongst it than they do in peat, and this year I intend trying a number in living moss only. It is important when potting is done that the plants be well elevated above the rim of the pots, for experience proves to me that the higher they can be raised with safety the better they will flourish. It will be found in the cultivation of those mentioned last that they root much more freely near the surface than they do at any depth below, neither will the roots that descend be found when turned out in the same healthy condition as those in the compost above the rim of the pots. This is not the case when the roots ramble freely amongst the crocks and charcoal used for drainage, but when a good depth of compost is used below the rim of the pots. I have been turning out a number lately, and all that have the least depth of moss and peat below the surface are all the best rooted plants, and have made the strongest growths. These plants are not of strong-rooting habit, and do not therefore require large pots or any great depth of material to root in. After potting I have found the plants to do better when elevated upon small pots, or anything else used as a substitute, than they do when standing directly upon the gravel or other material of which the bed may be composed. I do not care to stand them upon wood trellis-work unless it can be arranged close over shallow tanks of water, for the plants and their surroundings become dry too rapidly during bright weather when air has to be given abundantly. If elevated only 1 or 2 inches above the material forming the bed it is ample, and allows superfluous water to pass away and air to circulate freely amongst the plants.—W. BARDNEY.

OLD PRIMULA PLANTS.

WHEN their season ends and other more showy flowers appear it is often thought that old *Primulas* are not worth keeping for another winter, but plants which have produced blooms of the finest form and colour are valuable. In the best selected strains we find the flowers vary in size and colour, and as the true variety may not always be easily obtained or preserved, they have often to do service for at least two and sometimes three years. Many of our one-year-old *Primulas* are grown in 4-inch pots, and when one season is over in these they are transferred to 6-inch pots. They generally advance well, and by the second autumn they are much finer plants than they were before. Those in 6-inch pots are sometimes placed in a larger size, and others are only turned out of the pots, the ball reduced, and again potted in the same size. I am sure if many cultivators would try these ways of dealing with the best of their old *Primulas*, they would find them as good or possibly better than any of the young plants they could raise from seed. Potting may be done at any time, from now until May; and the cold frame treatment, which suit seedling *Primulas* in summer, will be found to agree equally well with the old plants.—M. M.

KEEPING RABBITS FROM A GARDEN.—I see a correspondent in the *Journal*, March 13th, seeks information in keeping rabbits out of his garden. No one is more troubled with rabbits than I have been, as I am situated in the middle of a wood; and just outside the garden boundary

there is a rabbit burrow with sixteen holes. I have seen them jump over our wire fence 4 feet 6 inches in height, and have had to add another foot of wire to bend over. Still they get in while the carriage gate is open. After trying several experiments we have just found a remedy. I obtained some old wool and petroleum. A little petroleum is placed in a pan and the wool rubbed round it so as to carry the smell, and it is then laid round a few plants which they visit. They will not come anywhere near it. Since using the above I have only seen one rabbit, and that I shot. I believe they can smell it outside the garden. We have a dog by the side of the house, and a small path 5 feet wide leading from the wood, and have proved that rabbits come very near to the dog at night by laying sand across the path, which show that they are very daring in their hunger.—R. C.

VINE ROOTS—MANURING VINES.

I AGREE with what is said on page 442 that artificial manures will not attract Vine roots "through a mass of soil 1 foot or 2 feet thick," but I go further and say no manure of any kind will do that. I have, however, a vine in which the roots of the Vines have been attracted to the surface of the border solely by means of Standen's manure, which has been applied every year for about seven years. Above the manure was spread loam sometimes, and sometimes it was only slightly forked in, and a light mulching of leaf soil was always put on above all, but only about 3 inches, and that was always swept off again at the next dressing. Once, two years ago, cow dung was applied as well as Standen's, but the roots were plentiful then. It is essential to keep the surface moist with top-dressings, otherwise rooting will not go on, but any appropriate Vine manure will induce fibrous roots under such conditions. Our Vines in pots were never manured with anything but Standen's manure, and the abundance of fibrous roots produced by it first determined us to apply it regularly to the borders as a surface dressing. I notice wood ashes are recommended with loam to be applied at first to produce fibrous roots, which "will then form readily, and a million mouths be provided for, appropriating the food that may afterwards be given." Chemists describe wood ashes as an excellent artificial fertiliser, and it has been proved to be particularly serviceable to the Vine, containing, as it does, Vine food in a concentrated form.—CASUAL.

NEW PLANTS AT REGENT'S PARK.

A LARGE number of new plants was as usual shown at the Royal Botanic Society's first spring Show last week, some being especially meritorious. Several of those certificated have been previously honoured at Kensington and described in the reports of the meetings. The following were thus twice honoured—namely, *Adiantum rhodophyllum*, *Dieffenbachia Jenmani*, *Hyacinth Harlequin*, and *Amaryllis* Mrs. Shirley Hibberd, Col. Burnaby, and Sir Redvers Buller from Messrs. Veitch & Sons, Chelsea; *Odontoglossum macrospilum* from Mr. B. S. Williams, Upper Holloway; *Cattleya Trianae* Leeana, *Odontoglossum Oerstedti*, and *Masdevallia Schlimi* from W. Lee, Esq., Downside, Dorking. In addition to these the following were certificated—

Masdevallia Chelsoni (Veitch and W. Lee, Esq.).—A showy form, somewhat suggestive of *M. Veitchiana* in colouring—a kind of shining orange-red; but the flower is smaller and without that peculiar violet gloss which renders *M. Veitchiana* so beautiful. It is free, and apparently of sturdy growth.

Azalea La Merveilleuse (Veitch).—A magnificent single variety of the *A. indica* type, with finely formed intensely rich crimson flowers, 3 inches across; the petals rounded, broad, and of great substance. The plant is sturdy and compact in habit and very free.

Hyacinth Minerva (Veitch).—A double variety; the bells very full and well formed, of a peculiar salmon colour tinted with rose.

Hyacinth Lord Derby Improved (Veitch).—The single light blue *Hyacinth Lord Derby* is well known, and of this the variety now noticed is an improved form with larger more massive spikes and bells. A very handsome form.

Amaryllis Madonna (Veitch).—Flowers with broad rounded petals, charmingly veined and streaked with crimson upon a white ground. Very delicate and chaste. The plant shown had two spikes with two flowers each.

Muscari concinnum (Douglas).—A charming *Grape Hyacinth*, somewhat of the *M. botryoides* type, with compact spikes of large bright blue bells. Very free and dwarf; pretty in pots as shown by Mr. Douglas.

Cypripedium Druryi (Williams).—A small-flowered but distinct species; the sepals and petals yellowish with a green tinge, each having a median maroon stripe, which is very strongly marked in the dorsal sepal. The lip is buff yellow.

Adiantum strictum (Williams).—One of the *A. cuneatum* type with small pinnules, and having closely set erect fronds, from which character the name is derived.

Odontoglossum Wilckeanum Littlei (Little).—A beautiful variety, a really fine *O. Wilckeanum*; the ground colour pale yellow, heavily spotted with chocolate on the sepals and smaller dots on the petals.

Cyclamen Dame Blanche (H. B. Smith).—Remarkable for the great substance of the flowers, which are about 2 inches long; the petals being an inch broad, pure white, and of neat form.

Cyclamen Purity (Little).—Very free; the flowers pure white, but only of moderate size.

Cyclamen Rose Gem (Little).—Exceedingly free. A bright rosy self flower of good form and produced in great numbers. Most valuable for decoration.

Cineraria Prince of Wales (James).—A large, handsome, rosy crimson self. Flowers 2 inches in diameter and very rich in colour.

Cineraria Venus (James).—A rich crimson-maroon self, with broad petals of fine substance and velvety gloss.

Cineraria Sir F. Roberts (James).—A magnificent variety, crimson-purple; the flowers 2½ inches in diameter, of wonderful substance.

Cineraria Mrs. Arden (James).—Very large and showy; flower rosy crimson with a white ring in the centre.

Cineraria Lottie Williamson (James).—Distinct in colouring, the body colour being a rich purple-maroon, with a bright rose central ring. The flower is smooth and of good substance.

Auricula Sir W. Hewett (Douglas).—A maroon self Show variety with large blooms, six in a truss. The colour is extremely rich, but the paste is narrow though well defined.

Auricula General Gordon (Douglas).—A white-edge Show variety, with deep purple body colour, even edge and paste; the flower generally neat. Truss large and strong.

Auricula Mrs. Moore (Douglas).—A green-edge variety. Flowers large, black body colour, small paste, but even and well defined.

IMPNEY,

THE SEAT OF JOHN CORBETT, ESQ., M.P.

THE name of Impney has of late become somewhat familiar to readers of garden literature, inasmuch as the gardener there was appointed as the successor of the late lamented Mr. Thomas Speed at Chatsworth. This implies that Mr. Corbett's gardens possess some features of interest, and that their condition is worthy of note. Both propositions are well founded. In one important respect Impney is more than interesting, it is wonderful; and as to the keeping of the grounds and gardens, it was not until they had undergone a searching inspection by the representative of the Duke of Devonshire that Mr. Owen Thomas was offered the opportunity of filling the position on which he entered a fortnight ago; and this, it may be mentioned here on precisely the same terms, and invested with exactly the same authority as his predecessor. But to Impney.

It is no old baronial estate of historical note, with a venerable mansion hoary and worn with the lapse of centuries. The owner of the estate is not, to coin a term, an inheritor of history, but a maker of it. Impney is indeed a splendid memorial of nineteenth-century commercial progress and success, and in this respect has few equals in this country. "Diligence in business" has in the remarkable career of Mr. Corbett brought a striking reward, and the "salt of the earth" has literally proved its virtues in a manner that is quite extraordinary.

A stranger arriving in Droitwich and asking what is the staple trade of the town, would receive in reply, "Salt, all salt." The quaint old town, though not indicating the fact by its whiteness, rests on salt, lives by salt, and is, in fact, sinking into salt, not a few of the houses appearing to the stranger as dangerously likely to be "cured." There are tall black chimneys all over the town, and at the base of them furnaces for boiling the brine and converting into salt. The brine is pumped up year after year by powerful steam pumps from wells sunk from 300 to 1000 feet deep, dissolving and wearing the salt rocks till hills have become hollows, and the sinking and slanting houses appearing as if putting their heads together, like certain old fogies who do not rejoice in the "bit of blue." The inhabitants, however, appear to be contented, and the town prosperous, the celebrity of its brine baths attracting thousands of sufferers from all parts of the British Isles, as well as the continent and America, every year. The town is so crowded with bathers suffering from rheumatic gout, sciatica, nervous debility, and other diseases of the nerves, that it is often difficult to lodge them all, and the cures effected are often marvellous. It is at the Stoke Works, however, about three miles from Droitwich, that the magnitude of the salt industry is the most apparent. Here there are some sixty or seventy tall shafts, and from two to three thousand persons are dependent for their livelihood on this great establishment. Those works belong to Mr. Corbett. By his own industry and remarkable business aptitude he reared them, and, as if this was not enough, he made Impney what it is to-day.

Some fourteen or fifteen years ago he purchased a large tract of land, a purely agricultural district, somewhat boldly undulated. The land that consisted of ploughed fields then is a beautiful park now, well furnished with trees, and beautified with water, while a herd of deer fatten on the rich herbage of the fertile soil. The mansion, which is beautifully situated, and commands extensive, diversified, and picturesque views, is in the French style. It is a most imposing pile, the material (hand-smoothed bricks, with stone facings) and workmanship being of the best possible character; and the architectural embellishments singularly rich. It is estimated that £100,000 was expended in its erection alone. The roof of the hall or vestibule is supported by massive and solid pillars of marble, everything being in keeping; and valuable paintings of the old masters Titian, Rembrandt, Vandyke, and others adorn the walls.

On the south side of the mansion are spacious terrace gardens with flower beds in panels, an elaborate fountain, and splendid specimen Hollies, Cupressus Lawsoniana erecta viridis, Golden Yews, and Retinosporas appropriately placed on the lawn. The walks, which are wide, are made of asphalt, the kind known as *Val de Travers*, and are level, durable, pleasant to walk on, and not dingy in appearance. The view from the terrace is particularly fine, embracing water, bridges, trees, a far-reaching pastoral valley, and, beyond, the Malvern Hills. A striking feature, and a most useful one, is a remarkable densely tree-clad hill or small mountain, which rises a few hundred yards from the mansion and completely masks the town of Droitwich. Round the base of this eminence a wide stream rushes along its tortuous course, and has afforded an opportunity for forming cascades. These have been admirably contrived and executed, and they contribute powerfully to the beauty of a beautiful place. Passing along under the arcades of Willows the "music of the waters" is almost deafening, while the wild flowers on the steep hillside are scattered in profusion. The mound is ascended by long curving flights of rugged steps, and the wooded hill is intersected by serpentine walks quite canopied with foliage during the summer months. The extent of

this picturesque eminence is about thirty acres, and it is undoubtedly one of the principal charms of Impney. It was from a position on the hill that the photograph was taken from which the engraving has been prepared. It is one of a series of several others which have been successfully executed by the London Stereoscopic Company, and affords an idea of the attractiveness of the surroundings of the mansion. No expense has been spared in rendering Impney what it is. The leading landscape gardeners have been employed from time to time, and Mr. Owen Thomas was busily occupied during most of the time he was at Impney carrying out important improvements suggested by himself or Mr. Corbett, and has left the marks of a master hand behind him.

The gardens are a short distance, nearly a quarter of a mile, from the mansion, and from which they are partially hidden by the configuration of the ground and shrubberies. The work of tree and shrub-planting has been conducted on a scale of no small magnitude, as may be imagined when it is estimated that shrubs and trees of the value of £10,000 have been planted since the work commenced, many of the first planted having died; but there have been few failures lately, as both trees and shrubs are established and in a healthy flourishing state. As an instance of success in transplanting, a number of large specimen Lime trees were purchased in Surrey last May, the trees being forthwith removed, although bursting into leaf. At least some of them were expected to fail; but by careful packing, immersion in the lake for a few days after their arrival, and subsequent care every one has grown satisfactorily.

The kitchen gardens are not extensive, between two and three acres being enclosed between lofty walls, which are covered from base to summit with healthy fruit trees, although these have only been planted about six years. Similarly fine are the pyramid trees in the garden. Considering their age, finer, cleaner, and more fruitful examples have never been seen. No moss, no canker, but clean bright wood everywhere, and the varieties are as choice as the trees are excellent. These trees were planted by Mr. M. Temple, now of Carronbridge, and Mr. Thomas gives him ungrudgingly the praise he so well deserves for the excellence of his work. The soil around Droitwich being impregnated with salt was found by its effect on Vines not to be depended on for fruit culture, hence turfy loam was imported from some distance, and the wisdom of the step is now apparent.

Erected against the south wall of the kitchen garden is a range of glass structures such as is not seen every day. It was erected by Messrs. Clark & Hope, of Birmingham, at a cost of £3000. For strength, lightness, and durability these houses could not be surpassed. There is no wood employed, the framework and doors being of iron and the woodwork of brass. The range is in nine divisions—namely, two Peach houses about 50 feet long, lean-to's; three splendid lofty vineries with hipped roofs to the north, the rafters facing south being apparently over 20 feet long; two span-roofed plant houses about 32 feet long, at right angles with the others; a Fig house 20 feet, and a small octagonal fernery in the centre of the range. Nothing more clean, orderly, and satisfactory than this range and its contents could well be imagined. Peach trees in the best of health and bearing the best of crops, Vines starting strong and freely, those in the early houses showing bunches plentifully, the retention of young wood, not rigid spur-pruning, being the system relied on for the production of Grapes.

Plants of all kinds were as healthy as the fruit crops were promising, *Cinerarias* especially being noteworthy by their vigour and the excellence of the varieties. Messrs. F. & A. Dickson of Chester, who supplied the seed, evidently possess an excellent strain of these effective spring flowers. Standard *Maréchal Niel* Roses were showing buds freely preparatory to forming golden heads of flowers. Standard *Heliotropes* were in preparation, and these in due time will find many admirers. In the cool stove *Abutilon Sellowianum marmoratum* showed to great advantage associated with dark-foliaged *Dracaenas*, while Palms and other foliage plants were in the best of health.

Outside the garden and in what might be termed the frame ground is a range of extremely useful pits about 250 feet long. They are low narrow serviceable structures with a path down the centre and beds on each side, everything on them and suspended from the roof being within easy reach of the cultivator. Such cheap, handy, serviceable structures ought to be more frequently seen, as they are so useful for a variety of purposes, and so profitable. Plants of various kinds are raised in the range under notice. Kidney Beans, Strawberries, and Asparagus forced, Melons and Cucumbers produced in abundance, Davenham Early Melon being highly esteemed for its precocity and good quality, while in three of the divisions Pines are grown well, dwarf stubby-leaved plants in 8 and 9-inch pots, showing fruits that will be considerably larger than on hundreds of plants that occupy twice the space. This is the Drumlanrig system of Pine culture—small plants and large fruits which reflect so much credit on the cultivators.

On the south side of the kitchen garden at Impney, outside the walls, is an extremely enjoyable rosery. The Roses are planted in beds, dwarf plants with long strong shoots pegged flat to the ground instead of shortening them. That is the way to produce Roses that can be cut by the basketful for decorative purposes, and fine blooms into the bargain. The Rose buds are relieved by choice shrubs, and thus the enclosure has a furnished appearance in the winter. The west outside screen is occupied with a series of buds of herbaceous plants for affording flowers for cutting, the beds being sheltered by a contiguous row of flourishing *Wellingtonias*. There is also a garden of Alpine plants, but rockeries are wanting to show them to advantage. These will no doubt be supplied in due time, for nothing is denied to complete whatever is taken in hand in these admirable and excellently kept gardens.

Adjoining the mansion is a small conservatory attractively furnished, the fine-foliaged plants, such as Palms, also Camellias, being remarkable for the richness and gloss of their deep green leaves; while the Tree Ferns are growing with extraordinary vigour. This is due in a great measure to encasing their stems with peat covered with moss, and giving them now and then a solution of Clay's fertiliser, for which they well repay by their exuberant fronds. In reference to the glass structures and their contents it would not be just to ignore the good work of the foreman in charge, Mr. W. Saw, who is well educated, intelligent, and industrious—qualities that should be possessed by all young men who aspire to good positions in the gardening world.

Gardening, however well conducted at Impney, is only a small part of the gardener's duties, outside improvements and the general management of the home estate devolving upon the gardener. That Mr. Thomas was equal to all his duties is beyond a doubt, and Mr. Corbett afforded him the best possible testimony of his worth; he also presented Mrs. Thomas with a splendid gold watch as a graceful tribute of respect to herself and

to its rather delicate constitution, which under the best management often causes it to be badly attacked by mildew, which weakens the plant and renders it more liable to be attacked another season, until at last it dies. The application of sulphur in one or other of its various forms is the best remedy for this pest, at the same time keeping the plant in a healthy growing condition, the house dry and well ventilated, but avoiding all cold draughts and extremes of temperature.

Prevention is always better than cure, and the more vigorously and hardy the plant can be grown the less likely will it be to fall a prey to mildew or any other disease. The system of culture pursued here has been before alluded to in these pages, and certainly deserves to be widely known, as it gives us an abundant supply of the finest flowers possible year after year.

The tree is planted in the centre of a narrow border about 3 feet wide, and running the whole length of the house, but doubtless its roots have rambed far beyond the bounds allotted to them. The house is 28 feet long by 12½ feet wide, and is quite cool, no fire heat being used. A main

FIG. 63.—IMPNEY.

her husband. The *employés* on the home estate also gave practical evidence of the esteem in which they held their chief who, though a strict disciplinarian, is uniformly considerate and courteous to all, by presenting him with a handsome walnut writing cabinet and inkstand, accompanied with an appropriate letter asking his acceptance of their offering.

As Impney has had a good gardener in the past there cannot be a doubt that a good one is provided for the future in Mr. Richard Parker, for no one could remain in such a place as Hutton Hall, and under such a master of the art of cultivation as Mr. McIndoe, without being fully competent, and the elected from 400 applicants is congratulated on his appointment to what was—and there is no wonder that it should be so—a much-coveted charge.

Besides keeping his estate in such perfect order, Mr. Corbett is a benefactor to the town of Droitwich, which he represents in Parliament, and the district surrounding. Everything that is worthy has his countenance and support, and the public buildings he has erected, both as regards their use and ornament, reflect the practical mind, the good taste, and the generosity of the affluent owner of Impney.—J. WRIGHT.

THE MARÉCHAL "NIEL" ROSE.

THIS has become such a general favourite with all classes within the last few years that almost everyone attempts its cultivation, and yet it is very seldom we see a vigorous plant of it. This is, perhaps, partly due

branch extends horizontally on each side of the plant to the end of the house; wires 1½ foot apart are carried from this to the top of the house, and on each of these three young shoots are trained each year, as we cut the old ones down to within three eyes as soon as they have done flowering, and train the three best shoots up again for the following year's crop of flowers.

Two branches from this plant also extend horizontally into an adjoining house, a length of 28 feet. In 1883 we commenced cutting April 20th, and continued until the second week in June, cutting in all 115 dozen of handsome blooms. All the pruning required in the spring is merely to take off the unripe points of the shoots before the buds start for flowering. These shoots are often over 16 feet long and of proportionate thickness.—W. H. DIVERS, *Burghley*.

ORCHID NOTES.

CUTTING DOWN DENDROBIUMS.—Will your correspondent, "B.," kindly excuse me asking him for more precise particulars regarding his practice in this matter? as I am interested in it myself, and perhaps "B." is aware the practice is one which has been much disputed of late. First, How many years in succession has "B." cut away the flowering pseudo-bulbs from any one of his plants, and have the annual growths (pseudo-bulbs) grown stronger, or weaker, or maintained their vigour since under the treatment? May I press

your correspondent for an accurate reply to this, for which I shall feel obliged to him? I am inclined to think he is right, but his note this week is not very clear to me.

Second, he speaks of "the young growths starting from the base of the old pseudo-bulbs that had been taken away," whereas, in a regular way, the young growths of *D. nobile* do not proceed from the base of the flowering pseudo-bulbs at all, but from the base of the last year's pseudo-bulbs. It is the two-year-old pseudo-bulbs that flower, hence there must of necessity be always two years' pseudo-bulbs left on the plant till blooming is over. For example, "B.'s" plants should now be carrying their last year's growths, which will flower twelve months hence, and the young growths will be pushing from the base of these, not from the cut-away flowering pseudo-bulbs.—J. S.

ODONTOGLOSSUM EDWARDI.—Numerous as are the species and varieties of the *Odontoglossum* now in cultivation, the subject of the present note is eminently deserving of attention, as it is one of the most distinct of the whole genus, and possesses special attractions of colour to recommend it. A plant is flowering at Kew which shows its characters to the best advantage, having two strong spikes, one with nine branches bearing eighty-three flowers and buds, the height 3 or 4 feet. The flowers are about an inch in diameter, with narrow sepals and petals undulated, and with the points recurved. The colour is a uniform purplish mauve with a tinge of violet quite distinct from any other *Odontoglossum* and from the majority of Orchids, except some of the *Bollea* type. In contrast with *O. Pescatorei* and *O. Alexandræ* it is most striking, and as it succeeds well in a cool house with those species it is particularly valuable. The plant has been grown at Kew for some years, but was first imported in quantity six years ago, though it still continues scarce.

ODONTOGLOSSUM ELEGANS.—A beautiful Orchid, remarkably like a large and dark-coloured *O. cirrhosum*, but with the petals less waved and broader than the majority of forms of that species. The spots are very large, almost covering the sepals, a little smaller on the petals, but equally dark. It produces a graceful spike, and is of robust habit when grown as Mr. Pollett has it at Bickley.

CATTLEYA TRIANA LEEANA.—High prices for Orchids are by no means uncommon now, but it is seldom that 250 guineas is given for a single plant. Yet this is the price paid by Mr. W. Lee, Downside, Leatherhead, for the superb *Cattleya* which bears his name, and for which certificates were granted last week by the Royal Horticultural and the Royal Botanic Societies. Numerous varieties of *C. Trianae* have been introduced to cultivation in recent years, some having originated in this country, but the majority are imported plants. These present considerable difficulties in the size and colouring of the flowers, but there is no question that they are all surpassed by Mr. Lee's magnificent variety. The plant is a fine one, growing upon a large block of wood and having about thirty pseudo-bulbs, rather tall and somewhat cylindrical. The flowers are 7 to 8 inches in diameter, the petals 3 inches across, pale mauve-purple, the petals being of similar colour but more narrow. The lip is of wonderful size, fully 4 inches long and 3 or more in breadth, of a most intensely rich magenta-crimson colour extending far into the throat. This plant is the only specimen of the variety in cultivation, and it is not at all likely to be excelled by new importations.

THE DAFFODIL CONFERENCE AT SOUTH KENSINGTON.

APRIL 1ST.

SUCCESS in an unqualified degree attended the efforts of the Royal Horticultural Society to obtain a thoroughly representative exhibition of Daffodils in all their numerous forms, for never before have so many flowers of the charming genus *Narcissus* been brought together. The idea was an excellent one, seasonable and novel, and proved most conclusively how much can be effected by pure enthusiasm without the offer of tempting prizes to induce exhibitors to contribute on such an occasion. Based on the same lines as the Apple Congress last year, though necessarily on a much less extensive scale, it was an equally good representative and non-competitive exhibition, the success of which may be confidently expected to lead to other schemes of a similar character.

The conservatory contained a vast array of golden, creamy, and pure white flowers, in all their variations, from the gigantic Trumpet Daffodils *Empress* and *maximus* to the diminutive minor and *minimus*, the delicately tinted "Peerless" varieties and hybrids, and the lovely wax-like *Poet's* *Narciss*, while the air was laden with the perfume of a thousand *Campanulæ* and *Jonquils*. Every gradation was there, and an unbroken chain of changing forms and colours could have been formed from the material afforded by the numerous collections. To enumerate the varieties would fill a volume, and, after all, verbal descriptions of such flowers, as Mr. Baker subsequently stated, would not convey an adequate idea of their characters. A few notes of the most distinct may, however, be desirable. By far the finest collection in every respect was that from Mr. James Walker of Whitton, Middlesex, the flowers being of great size, remarkably fresh, brightly coloured, or purely white, and indicating that their culture is well understood. They were also very tastefully set up in Hyacinth glasses, a dozen or more flowers being placed in each, and the base of the stalks surrounded with moss. A great number of beautiful varieties and hybrids were included, the *N. incomparabilis* forms

being especially abundant and handsome. Of these the following were noteworthy:—*pallidus* *Princess Mary* of Cambridge, pale yellow petals, and a wide rich orange crown; *albus* *Milneri*, broad creamy white petals, crown wide, rich orange fading to yellow at the base; *Minnie Hume*, broad pure white petals, clear yellow open crown; *albus ruber aurantius*, petals white, crown an intensely rich orange. The double form *albus aurantius plenus* was admirably shown, the flowers large, pure white, and orange. Of other notable varieties near these the best were *Leedsii amabilis*, with white spreading petals and straight faint creamy-yellow crown; *Nelsoni major*, petals white, with a straight orange-yellow crown, deeper towards the edge; and *cernuus pulcher*, with white petals, and very long pale yellow crown. *N. odoratus*, *N. Jonquilla*, and *N. Tazetta* were in large numbers and fine condition. *N. Pseudo-Narcissus* and its varieties formed another important portion of the collection; *bicolor anceps*, the golden *spurius*, the rich and large *maximus*, *Emperor*, *Horsefieldi*, and scores of others being grand in every respect. *N. poeticus*, with its varieties *ornatus* and *tripodalis*, and the nearly allied *N. Burbidgei* formed another charming group, while the *Hoop Petticoat* *Narciss* was freely employed amongst the others with excellent effect.

Messrs. Barr & Son, King Street, Covent Garden, contributed a most extensive collection of flowers, comprising some hundreds of choice varieties and hybrids. All the sections were exhibited in due proportions, a grand group of the Trumpet Daffodils at one end presenting a series of beautiful shades of gold and orange, the handsome crowns being contrasted in the case of the *bicolor* forms with pure white petals. Large clusters of fine double Daffodils imparted an additional interest to this portion of the exhibit. The forms of *N. incomparabilis* were shown in scores, some being extremely pretty, with the *Leedsii* and *Barri* groups. Very noteworthy was *N. incomparabilis aureo-lineatus*, with a rich orange crown of wonderful colour; another was *concolor*, with clear yellow petals and pale orange crown, very delicate. *Leedsii galanthiflorus aurantius* is a charming *Narciss*, with pure white petals and a deep orange-yellow crown. *Leedsii amabilis* with pale creamy flowers, and *Barri conspicuus* has broad well-proportioned petals and crown tipped with orange scarlet, one of the most distinct and handsome of all. *N. incomparabilis* *Queen Sophia* of the Netherlands is also a very striking variety with broad rounded petals and an extremely rich gold crown. Amongst the *N. cernuus* family a variety called *Rebecca Syme*, or the Violet-scented Daffodil, is remarkable for its sweet delicate odour, the flowers being of a pale lemon colour. *N. odoratus rugulosus* is a pretty single form of the *Campanelle*, with which were shown numbers of *N. odoratus minor plenus*, *Queen Anne's* double Daffodil, very neat in form, full, and of a rich golden hue. *N. poeticus* was represented by some superb varieties, *poetarum* having the deepest coloured crown; while of the allied *N. Burbidgei* two handsome variations were shown, named respectively *expansus* and *grandiflorus*, the former having a very broad beautiful crown, and the latter distinguished by its unusually large flowers. *N. Bulbocodium* contributed to the interest of the group, the early small-flowered pale variety *nivalis* being noteworthy, together with the charming little *Corbularia Graelsii*, the petals of which are inconspicuous and greenish, the crown pale gold and very large. These are but few of many excellent Daffodils shown by Mr. Barr, for in number of distinct forms this was the most complete of all those present. In the central portion of the collection the bottles containing the flowers were concealed beneath a bank of moss, amongst which were also dispersed a few plants of *Isolepis gracilis*, *Aralias*, and *Ivy*. This had a much more pleasing appearance than the usual formal style of setting up these flowers, and might be advantageously imitated on a more extensive scale. It should be added that a most welcome glow of distinct colouring was furnished by a collection of the brilliant *Auemone fulgens* from Mr. Barr at one end of the conservatory.

From Mrs. Vivian's garden at Singleton, Swansea, a collection of miscellaneous Daffodils was sent, and Mr. J. T. D. Llewelyn contributed some wild Daffodils gathered in the woods near Swansea, amongst which were examples of the Tenby Daffodil, *N. obvallaris*, a neat-flowered early variety, together with a general collection of garden flowers, *N. bicolor* *Horsefieldi* being wonderfully fine. Mr. W. Brockbank, Didsbury, Manchester, sent some flowers of the Tenby Daffodil, found wild in Pembrokeshire, some pretty forms of *N. cernuus*. Mr. F. W. Wilson, Weybridge, contributed some choice blooms of *N. Pseudo-Narcissus*, *N. incomparabilis*, *N. Tazetta*, and some pretty *Jonquils*. Mr. J. Fitt, gardener to the Earl of Essex, Cassiobury, Essex, sent a collection of double and single Daffodils; and New Plant and Bulb Company, Colchester, had a good general collection.

Messrs. J. Veitch & Sons, Chelsea, had an extensive collection, the flowers arranged in boxes of moss, a number of flowers of a few leading varieties being shown. *N. poeticus*, *N. bicolor* *Horsefieldi*, *N. Telemonius plenus*, *N. cernuus pulcher*, *N. rugulosus*, *N. incomparabilis* *Leedsii expansus*, *N. odoratus* and *minor plenus*, *N. spurius*, and *N. incomparabilis sulphureus plenus*, which was especially handsome. From the Society's garden at Chiswick a number of select varieties were contributed, and Mr. T. S. Ware, Tottenham, had a handsome collection of the best forms, representing all sections. Mr. R. Frisby, gardener to M. H. Farrington, Worden Hall, Preston, sent some flowers of the wild double *N. Pseudo-Narcissus*. Capt. C. G. Nelson, Holme Lodge, Godalming; Mr. E. G. Loder, Floore Weedon, Northamptonshire; Mr. H. J. Elwes, Preston House, Cirencester; and Mr. F. W. Moore, Curator, Glasnevin Botanic Gardens, also sent small collections of flowers, including some choice varieties. Some particularly handsome bouquets of Daffodils and Ferns were exhibited by Messrs. Dickson of Covent Garden, R. Morgan of South Kensington, and Aldous of Gloucester Road, all of which were greatly admired by the visitors; but a group which attracted much the largest attention was a tasteful free arrangement of Daffodils with shoots of hardy shrubs from Miss Jekyll, Munstead, Godalming. Only a few of the boldest and most distinct varieties were employed, but so gracefully were they associated with the foliage that their appearance was most pleasing.

Mr. E. H. Krelage, Haarlem, showed some spikes of *Hyacinth* *Charles Dickens*, one half red and the other blue, showing the reversion of the red sport to the original blue variety. Flowers of *Scilla italica alba* and *Chionodoxa nana* were also sent. Mr. Davidson, Iwerne Minster, Shaftesbury, sent flowers of seedling *Imantophyllums*, very fine, and several large heads of *Rhododendrons* were sent from Singleton.

A great number of Fellows of the Society and visitors assembled durin

the morning, and when the Conference was opened the conservatory was crowded. Professor Foster took the chair at 1 P.M., and, after a few introductory remarks, called upon Mr. Burbidge to deliver the lecture, which had been previously announced, and of which the text will be found on page 260. It was read in a clear and pleasing manner, and was listened to very attentively by the large audience, who cheered the lecturer heartily at its conclusion.

At the conclusion of Mr. Burbidge's lecture the Chairman made a few complimentary remarks as to the completeness and excellence of the discourse, and then called upon Mr. Shirley Hibberd, who gave the following observations:—

Mr. Baker's classification of Narcissi comprises three groups, ordered as to the relative length of the crown, and twenty species, a few of which are certainly in the nature of accommodations, while others have but a frail tenure. As a system of classification it is undoubtedly the best we have, and the only one that is now worth serious consideration; but its weak points are strong for the purpose of instruction, and the hypothetical hybridiser would make ruin even out of many of the species. This hypothetical hybridiser we are bound to keep in view, for he is the practical critic when we enter upon the consideration of the origin of species, and is likely to tell us more about it than we ever dreamt of in our philosophical philosophy. Mr. Darwin recognised the aims of the florists as tending to the solution of biological problems; but many of his disciples are simply shocked at his largeness of view, and put their own personal vanity in the place of facts that have been established by workers in the garden. Within a few years we have witnessed the impress of the florist's hand in the world of Daffodils; and Mr. Backhouse, Mr. Leeds, Mr. Nelson, and other hybridisers, animated by the high floral inspiration that creates in it desires, have given us new races, new varieties, new forms, new colours in the newer population of the world of Daffodils. Their success most certainly marks their recognition of specific distinctions. For the purposes of the hybridist the determination of minute distinctions is waste of time, and the marriage of consanguinities as great a violation of biological as of conventional propriety. He requires distinctive types—marriageable certainly, but differing as widely as possible in complexion and feature. He will gain but little, and be very slow in gaining that little, if he restricts himself to crosses of closely related species. Thus, for practical purposes we are brought face to face with the question, "How many distinct types of Narciss are there amongst the twenty-one reputed species?" Opinions will differ, but I am here to say that after much thought upon the subject I can find no more than five. I will describe them very briefly. The Basket Daffodils are represented by *Narcissus Corbularia* or *Bulbocodium*; the Trumpet Daffodils are represented by *Narcissus Pseudo-Narcissus* in its many varieties; the Chalice Daffodils are represented by *Narcissus incomparabilis*, and perhaps by *Narcissus odoratus*; the Cup Daffodils are represented by *Narcissus juncifolius*, *Tazetta*, and *Jonquilla*; the Cymbal Daffodils are represented by *Narcissus poeticus*, *biflorus*, *serotinus*, and a few more. It is a pretty question whether we shall designate the corona of *N. odoratus* a chalice or a cup, and that pretty question carries us into the heart of the great subject of specific distinctions.

If I could dare to say that I feel inspired, then I would dare to say that there are no distinctions discoverable by the scientific mind in all the realm of Daffodils from the trumpets to the cymbals, from the baskets to the cups and saucers. We shall be true poets when we find them, because they exist solely in the imagination of the fanciful botanist. From end to end, no matter where you begin or where you end, the several kinds of Daffodils constitute a procession of the most delicate gradations. The species and varieties melt into each other in a way to defy scientific classification of missing links. I am not prepared to cite examples, but of connecting links there are any number, for they may all be regarded as such, and we may quote Pope's lines on the difficulty of dividing and separating, by saying—

"Whatever link you strike,
Tenth or ten thousandth, breaks the chain alike."

If we attempt to string them in the way of beads on one string we shall be perplexed at the separation of the largest from the smallest, for the gigantic Emperor and maximus, the largest of all the Daffodils, are next-of-kin to minor and minimus, the smallest of all Daffodils, or nearly so. For the illustration of this argument I will invite the students of the Narciss to consider how weak are such species as *calathinus*, *triandrus*, *poculiformis*, *Macleaii*, *dubius*, *gracilis*, *intermedius*, *pachybolbus*, *biflorus*, and some half dozen others. The difficulty of grouping, like that of species-making, is enormous. Let those who are disposed to undervalue the workers in this line of business try their 'prentice hands, and thereby learn to be modest.

In the year 1876 I proposed a classification founded on the number of flowers in a scape, and the recognised species easily fell into three groups for this purpose. They were Uniflorous, or One-flowered; Pauciflorous, or Few-flowered; and Multiflorous, or Many-flowered. This did very well until Nature cruelly produced a two-flowered trumpet Daffodil, and that reduced my classification to the level of a conundrum for which there is no answer. Thus, in one way and another, we return to our five types, which I believe will be the five species of the future, for species-making is scarcely a growing passion. We tend rather to consolidate than divide in our analyses of organic relationships; and to reduce the species of *Narcissus* from twenty-one to half a dozen or less will be a somewhat easy task for one familiar with the types and also with the methods and achievements by the hybridists. As for these last, they are bound to look for the most distinctive forms, the most loudly pronounced characters, in order to obtain new forms and new characters, and with them the vigour of constitution that fits a variety for an abiding place in the garden. If the hybridists can find more than five or six strikingly typical Daffodils it will appear that our studies of these flowers have thus far been too superficial to be of any use whatever.

Mr. H. J. Elwes, after remarking that he could not agree with Mr. Hibberd's method of classification, as most of the species as now defined are sufficiently distinct for all practical purposes, he would, however, restrict what should be considered as true species to those which had been found in a wild state. Referring to the nomenclature adopted, he thought it was very desirable that the naming of varieties and hybrids should be simplified as much as possible, and considered that it is exceedingly undesirable to bestow Latin names upon forms of garden origin. He advocated employing simple popular names, or the names of people, in preference to the cumbersome

designations which some Daffodils have received, and which have tended to a considerable degree to bring the plants into discredit. Mr. Barr's system of naming was specially mentioned as an example of the point in question. Remarking upon the distribution of Narcissi, Mr. Elwes thought the lecturer had not attached sufficient importance to that, for upon it depended a point of practical importance. Most of the Narcissi inhabited the south and south-western parts of Europe, and also in England, where the rainfall and the general humidity were greater. It was also found that the roots of the Narcissi, instead of dying each season like those of Tulips and most bulbous plants, remain fresh and more or less active throughout the year, therefore evidently needing a rather moist soil, and not being likely to be benefited by exposure to excessive summer heat or a very dry soil to insure that ripening which so many bulbs require. Commenting upon the variability of such plants under cultivation he considered that the botanist and gardener are mutually dependent upon each other, and only by a careful comparison of their observations could the limit of species be satisfactorily determined. He concluded by proposing that a resolution be passed to the effect that the method of naming garden varieties of Narcissi be simplified, as far as possible employing popular names in preference to those derived from the Latin or Greek.

In response to an invitation from Mr. Elwes and the Chairman, Mr. E. H. Krelage of Haarlem stated that in his opinion the practice adopted by the old Dutch florists for many years of giving common names to varieties of plants that were produced under cultivation was one that might be advantageously imitated by raisers of Narcissi. At the same time it is desirable to exercise some discrimination in bestowing names upon the very numerous forms obtained from seed, and which had caused many to denounce them as too much alike. It is, however, a matter of fact that the horticulturist who is paying special attention to any particular genus or class of plants becomes capable of detecting differences which a less-trained person would not notice. He thought also with Mr. Elwes that Holland is naturally better adapted for the cultivation of Narcissi than England; and he pointed out that though English growers had effected such great advances in the *Magnicoronatae* and *Mediocoronatae* groups, yet the *Tazetta* forms had received much more attention on the continent, and had been there grown for a number of years in very large numbers and of many varieties.

Mr. J. G. Baker of Kew was next called, and commenced his remarks by highly complimenting Mr. Burbidge upon the services he had rendered in connection with the Narcissus both as an artist and a writer, and observed how very important is the assistance of a skilled draughtsman in fixing the characters of the delicate gradations of many Narcissi, without which the work of the descriptive botanist is almost useless, as words cannot convey an accurate idea of some of the finer characters. He also considered that a public acknowledgment was due to Mr. Barr, who has done more than any other cultivator to improve the Narcissi and distribute them accurately named; and though he had employed the long descriptive Latin names objected to, he had simply followed the example of numbers of excellent writers and botanists of previous days. Still he wished to support Mr. Elwes' proposition with regard to simplifying the nomenclature of garden varieties. Mr. Hibberd's idea as to grouping was right in the main, but what he termed species Mr. Baker would regard as sub-genera, for the species that had been found in a wild state are readily distinguishable. In grouping, the terms genus, sub-genus, species, sub-species, and varieties are employed, the last-named being restricted to those found in a state of nature, and for these only he would employ true botanical names; for the two other divisions, garden varieties and hybrids, popular names are much preferred.

Mr. Barr said that his chief object had been to have his collection as accurately named as possible, and to this end he had consulted all the best authorities; but when these failed him he had relied upon his own judgment. He had at one time adopted such vulgar names as Codlins and Cream for some Daffodils, but had then been accused of deserting classical nomenclature; now he was in similar difficulty in the other direction. At the same time it should be remembered that he had employed the common names Leeds, Burbidge, Nelson, and Barri for groups of distinct hybrids, with which at least no fault could be found.

The Chairman then put to the Meeting the resolution proposed by Mr. Elwes and seconded by Mr. Baker, to this effect, "That in the opinion of this Conference it is desirable a more simple method of naming garden forms and hybrid Narcissi be adopted, and that popular or common names be employed for them in preference to botanical names." This was carried unanimously, but the Chairman expressed an opinion that it would be advantageous to appoint a committee of specialists to consider the whole question; and this was ultimately decided upon, the Committee to meet on the following day (Wednesday).

Mr. W. Brockbank of Manchester called attention to the double Narcissi which he thought had been somewhat neglected, for many are very beautiful and worthy of extensive cultivation. Referring to the structure of the double forms, he said it is curious that some of the double forms of *N. Pseudo-Narcissus* retain their stamens and pistil, producing seed freely, but he was not sure if the same character was observable in other double varieties, such as the *N. incomparabilis* group. Some discussion followed this, several stating that the double forms frequently bore seed which produced plants with single but never with double flowers, and Mr. Baker explained that in some cases the duplication was due to increase of perianth divisions, at others to the cutting up of the crown, to the metamorphosis of stamens or pistils, or of both; and thus in some cases the stamens might be present only, and in others the pistil only, the latter if fertilised by pollen from other flowers being of course capable of producing seed.

Mr. G. F. Wilson thought it was desirable that more attention should be given to the *N. Tazetta* varieties for cultivation out of doors. It is a common opinion that these are really greenhouse plants and much more tender than the other groups, but this he had proved was quite a mistake, for he had them growing freely in his garden at Weybridge.

There was some further discussion concerning the culture of particular species, in which Mr. Frank Miles, Mr. Short, and the Rev. Engelheart engaged, and the meeting then terminated with a cordial vote of thanks to Professor Foster, Dr. R. Hogg, and other members of the Council who had assisted in the scheme.

FORESTRY IN THE SANDWICH ISLANDS.—Considerable attention is being directed to forestry in these islands. A recent report says that a

century ago this country was in nearly every district fairly well wooded, and in some parts, now bare, was heavily timbered; but during the last fifty years it has suffered by the hand of the wood-chopper, the ravages of fire, the encroachment of cattle and goats, the attacks of insects, and the parching droughts, until many places where formerly the springs and streams never failed in summer or winter there is now no running water except in rainy weather. The animals eat the young trees, trample upon the roots, and in various ways weaken or destroy even the larger trees. The birds, accustomed to the dense shade and quiet of the woods, desert the places opened to the glaring light and drying rays of the sun, and the myriads of insects have it all their own way. Destructive and annoying insects have, like noxious weeds and grasses, been unintentionally introduced in the packing of merchandise and on plants and seeds, and there are not many insect-destroying birds to help in keeping them down. It is hoped that the attention which is now being directed to this important subject may cause a happy change to take place.

A TEA ROSE HOUSE.

WHAT favourites Tea Roses are! No flowers are more appreciated by the public; and they are especially valuable, as they may be had in bloom during the winter and spring, and again during the summer (their usual blooming period). It is, however, during the winter and spring that Tea Roses are more appreciated, and to have them then they must be grown under glass. No garden of any size should be without a Rose house, and the best I have seen is the conservatory at the King's Acre Nurseries, Hereford. This is a large structure, very light and span-roofed, with a well-prepared centre bed on the ground level, a walk round it, with a raised tan or leaf pit about 3 feet wide next the sides for growing Roses in pots. The artificial heat is supplied by flow and return 4-inch pipes. The centre bed is planted with standards principally, of different heights, the tallest in the centre, with other rows of different heights on each side. The front rows have stems about 1 foot to 18 inches high, with a few dwarfs. The roof supports, of which there are several throughout the house, have each a climbing Rose planted at the base of it and trained across the roof. Climbing Roses planted like these do not obstruct the light from those in the bed.

When Roses are planted out the bed must be well prepared and thoroughly drained. The greatest enemy is mildew, and this is induced chiefly by drought, faulty ventilation, and a cold stagnant atmosphere. Ventilate carefully at all times, and especially when the foliage is young. The house should have both top and under ventilators, but only those at the top should be opened during the early season of growth. It must be used so that it does not cause a draught. The pipes should be kept warm during the day whilst the ventilators are open, and if the pipes are painted occasionally with flour of sulphur it will assist in keeping mildew in check. The night temperature should be kept as near 50° or 55° as possible.

The border must never be allowed to become dry. When it requires watering give a thorough soaking of tepid water. If the bloom buds are well advanced supply liquid manure (if the plants are well established in the border) or a dressing of Clay's Fertiliser. Syringe the paths and border occasionally, and the foliage also on fine mornings before the blooms expand. The side beds are useful for plants in pots, as they can be removed to the conservatory whilst in bloom. The house should be fumigated occasionally to keep green fly in check. After the flowering season is over the house should be well ventilated to ripen the wood thoroughly, and do not forget a due supply of moisture at the roots. After the plants are pruned remove 2 inches of the surface soil and top-dress with some rich compost. The prunings are useful for cuttings if any plants are required on their own roots. If Roses on their own roots are not required these prunings make the best of grafts.—A. YOUNG.

RHODODENDRON FORTUNEI.

AMONGST the many beautiful shrubs for which we are indebted to the late Mr. Fortune, few are equal to the lovely Rhododendron which so worthily bears his name. Of a large and varied genus it stands out boldly in its characters, and though somewhat related to *R. Griffithianum*

in some respects, yet it is abundantly distinct and easily recognised by its superior rosy-coloured flowers. The leaves are elliptical, about 6 inches long, bright shining green with crimson footstalks. The flowers are borne in close heads of nine or ten, the corollas being 3 to 4 inches in diameter, with rounded spreading lobes, rosy on the outer surface and lighter within. In one respect the species is strikingly peculiar. The corolla has seven lobes and fourteen stamens. The large floret is of a soft pink colour, and has a very sweet odour. There is a yellow tinge in the centre of the corolla, and a well-grown truss is a very striking and beautiful object. It hybridises very freely with some other species and with hardy hybrids. Mr. Luscombe has raised some lovely seedlings between it and *R. Thomsoni*, which Messrs. Veitch possess. Some of my seedlings of the same strain have produced very grand flowers.

The true species, however, is most interesting. Mr. George Paul has a fine collection of plants of the first importation, and Messrs. Veitch of a subsequent importation by their collector. Judging by the foliage the

Fig. 64.—*Rhododendron Fortunei*.

two are alike, but it will be interesting when the second batch begin to bloom to compare the characters.

R. Metternichii of Japan has also in one of its varieties the peculiarity, very unusual in Rhododendrons, of the parts of the flower being in sevens.

R. Fortunei was discovered by Mr. Fortune in China, west of Ning Po, on mountains about 3000 feet above the level of the sea, where no other Rhododendron had been previously found, though at a lower level on the same mountains. Azaleas were very abundant. Seeds were sent to Mr. Glendinning in 1858 or 1859, and young plants were soon raised and distributed. It was, however, some years before flowers were

produced. It has been found to be quite hardy in most districts in the south of England. In the woodcut, fig. 64, a reduced flower and leaf are shown.—J. H. MANGLES, *Valerwood, Haslemere.*

NOTES ON ORCHIDS AT WESTBROOK, SHEFFIELD.

THIS place has long had more than a local reputation for its fine collection of Orchids, and which have been previously referred to in this Journal as being grown in close proximity to the extensive snuff mills, in which what is widely known as "Wilson's Top Mill Snuff" is manufactured, and with which the atmosphere of the Orchid houses is at most times heavily charged. The late proprietor, H. Wilson, Esq., was a great lover of Orchids, and spent large sums in their purchase and cultivation, and under the skilful management of his gardener, Mr. D. Clements, his became one of the best private collections in the provinces. In 1881, however, owing to the illness of Mr. Wilson, which eventually terminated fatally, a large portion of the collection was disposed of at Stevens' Rooms, and Mr. Clements left Westbrook to seek "fields and pastures new," which he soon found at Arnot Hill, Notts. For a year or two from then little was heard of "Orchids at the Snuff Mills," but at the present time a great revival appears to have set in. Mrs. H. Wilson and her son, Mr. Alfred Wilson, appear to unite in supporting their able gardener, Mr. Pidsley, who is an enthusiastic and skilful cultivator, and appears likely to soon restore the collection to much of its former excellence.

At the present time the flower house is exceedingly gay with a grand lot of Odontoglots and Dendrobies. The collection of Odontoglossums at Westbrook is especially fine, and well fills two span-roofed houses, each about 40 feet by 12 feet. The plants are in the most robust health, and are throwing up quite a small forest of flower spikes. I noticed *O. Alexandræ*, which had thrown up two grand spikes from one pseudobulb, one of which has twenty-seven and the other sixteen flowers. *O. Halli* has three spikes, two from one bulb, carrying eighteen, sixteen, and thirteen flowers respectively. *O. Andersonianum*, one of the best types of *Alexandræ*, has two spikes of fifteen and twelve flowers. *O. gloriosum* has sixty-two flowers on one spike, a beautifully densely flowered example. Of *O. gloriosum*, a pretty variety with much larger and brighter flowers than the type, has a good spike. Some very fine varieties of *Alexandræ* and *cirrhosum* are now flowering, and a number of plants of *O. nebulosum*. Amongst Dendrobies are some well-flowered examples of *D. crassinode Barberianum* and of *D. Wardianum*, amongst the latter is a most beautiful variety with pure white sepals, and petals very thick and waxy-looking; lip of the same colour, with very bright orange throat. A plant of *D. Ainsworthi*, which has just gone out of flower, carried 230 blooms, and is now making seven strong breaks.

Mr. Pidsley has lately repotted nearly the whole of the stock of Odontoglots in a compost of two-thirds fibrous peat to one-third sphagnum and charcoal. *Calanthes*, which he grows remarkably strongly, he is just repotting in a compost of equal parts of turfy loam, leaf mould, and decayed cow dung. He has a number of fine plants of *Dendrobium nobile* potted in about equal parts of sphagnum and bracken roots or rhizomes chopped small, in which the plants appear quite at home.—W. K. W.

HARDY FRUIT GARDEN.

Newly Planted Trees.—Un genial spring weather is very trying for newly planted trees. Failure, feeble or sickly growth, which attracts attention later in the year, often proceeds from such causes as careless planting, and subsequent exposure to the trying alternations of hot sunny days, cold nights, and dry parching winds. By careless planting negligence in any or every detail of the work is meant: to dig a hole that will barely hold the roots, to thrust them into it, and trample some soil hastily over them; to plant late after the sap is in motion, or when the soil is sodden with rain; to plant weakly or unhealthy trees; to leave the trees unfastened, so that they are liable to become wind-rocked and loosened in the soil; to plant in poor or undrained soil; or to apply no mulching of litter or half-decayed dung upon the surface over the roots. But if the trees were healthy and robust, and were planted in good time with due care in fertile well-drained soil, they will sustain no harm however changeable the weather may be. Attention is once more called to this matter, because even now much may be done to set right any negligence above the surface of the soil, and at any rate save the trees. The spring growth may, and probably will not be strong on trees suffering from carelessness, but they may be sufficiently recovered by midsummer to make good growth then. Should the weather in April prove very dry a liberal watering will much assist both root and branch growth in the young trees, and there need be no fear of overwatering if the drainage is sound. The soil generally is unusually dry for this season of the year. Many of what are termed "land springs," which begin to flow after

heavy autumnal rain, and cease to do so in summer, are already dry, which is fully two months before the usual period.

Sewage water may now be given with advantage to all bush fruits. It will tend materially to promote strong growth, fine vigorous blossom, and an abundant crop of large fruit. Strawberries, too, particularly in light thin soil, should have sewage early. The roots are now fairly at work, and the crowns already have the flower buds visible, and plenty of new foliage is opening and growing fast. Let us answer these calls of Nature promptly, and not wait till foliage is fully grown and blossom fully expanded, or we shall be too late to impart extraordinary vigour to both, which, we may add, ought certainly to be the aim of all good cultivators of fruit.

Grafting and Protection.—Bring up arrears of grafting as speedily as possible, and if clay is used look over the work occasionally and set right any premature cracking of badly tempered clay. We never use clay, but always hot grafting wax applied with a brush, the work being then well done once for all, and all risk from cracking avoided. With this, well-ripened scions, due care and skilful work, there need be no failures. Of protection we may usefully say, Be careful not to overdo it. Unless the blossom is advanced almost to opening protection is better away, so that by leaving the trees fully exposed to the air growth may be retarded as much as possible. The best way is to erect a framework over the trees to keep the coverings off, but close at hand till the blossom opens, and then to use it. If possible let the framework surround the tree, for it is not always that mischief comes from the north or east. Two years ago it was a south-western gale that battered the blossom to pieces, and literally scattered our prospects of fruit to the winds, excepting any trees that were sheltered on that side, all of which escaped harm and bore a crop of fruit. Also do not try to spread out the means of protection unduly; far better is it to protect a few trees thoroughly, and so make sure of some fruit, than to half protect many and risk the loss of an entire crop. There always must be some risk of loss in fruit culture, unless under very exceptional circumstances. Quite recently one of our large Kent fruit-growers stated at a public meeting that a certain frost caused him a loss of £3000.

FRUIT-FORCING.

VINES.—Earliest-forced House.—Examine the Grapes now taking their last swelling, and if any of the bunches are likely to bind take out a few of the least promising berries. Continue a moist genial atmosphere in the house, especially in the early part of the afternoon, closing for two or three hours with sun heat so as to secure the full development of the berries, admitting a little air afterwards so as to effect a circulation of air, and prevent the deposition of moisture on the berries during the night. Admit air early in the day, and liberally when the external conditions are favourable, leaving a little on constantly so as to produce a circulation of air after the Grapes change colour, and when this takes place gradually reduce the atmospheric moisture. If there be any deficiency of moisture in the inside border a thorough supply of tepid liquid manure should be given, and a mulch of short manure will prevent evaporation, keeping the mulching moist by damping occasionally, and this will keep the roots active near the surface, assisting in keeping the foliage healthy; plenty of moisture at the roots being even more essential in keeping the foliage free of red spider. Allow a moderate extension of the laterals, which will tend to keep the roots active, and to the keeping of the Grapes in good condition after they are ripe.

Succession Houses.—Disbudding, tying down the shoots, and stopping will require attention, as also will thinning the bunches and berries as the Grapes become fit. Allow the laterals to extend as space admits, and at the same time see that these are not allowed to interfere with the free access of air and light to the principal foliage. Muscats now in flower will require a high and moderately dry atmosphere to effect a good set, brushing over the bunches occasionally when the sun is bright and air has been given to liberate the pollen, and if there be a deficiency use that from Black Hamburgs. Although a somewhat dry atmosphere is advised when the Grapes are setting it must not be caused by admitting air so as to produce a current, and when the weather is bright moisture is absolutely essential as a means of support to the delicate young foliage. Remove the majority of the surplus bunches before the flowers open, thereby reducing the strain on the Vines, carefully fertilising those left for the crop with a camel's-hair brush, and if this were attended to we should see less stoneless berries. Water inside borders thoroughly, those swelling off their crops, and weakly Vines with tepid liquid manure. Close early at 80° with plenty of atmospheric moisture.

Late Houses.—The Vines in these are now making rapid progress, and will need disbudding, stopping, and tying before the young shoots reach the glass. If the space admits of the extension principle, stop two or three joints beyond the fruit, and allow the first set of laterals to fill up the vacant space, training the shoots sufficiently wide apart to admit of the full development of the foliage.

Keeping Late Grapes.—The winter has been so mild and dry that but little fire heat has been required to keep up the required temperature or to expel damp. Examine the bunches once or twice a week for decayed berries, and keep the bottles filled with rain water. Ventilate freely on fine mornings, closing early in the afternoon, and keep the windows closed in damp weather.

CHERRY HOUSE.—The growths that are reserved for supplying any deficiency of shoots which are required for filling up vacant space or furnishing the trees will now be sufficiently advanced to need

tying-in at the base. These and terminal shoots excepted, all the others should be stopped at about the fifth leaf. Syringe twice a day in bright weather, and once a day when the sun is not bright, until the stoning process is effected. The fruit must then be kept constantly dry, otherwise it will crack, spoiling its appearance and preventing its hanging. A dry atmosphere, however, will induce red spider; hence the paths should be sprinkled twice a day, and no injury to the fruit on the score of damp will ensue providing the house is duly ventilated at 55°. In order to have fine clean fruit the trees must be kept free from insect pests. If there be any trace of aphides fumigate moderately on a calm evening, and be careful to have the foliage dry, repeating if necessary, as it is very important that the insects be eradicated, and care must be taken in fumigation or the foliage will be injured. Before the final swelling a good watering should be given either with water or liquid manure, as may be considered necessary. Trees in pots will need special attention in watering. Admit air at 55°, freely ventilate at 60°, keeping it through the day at 70° or more from sun heat, and close at 55°. Turn on the heat early in the morning, so as to raise the temperature to 50° by 8 A.M., allowing the night temperature to range between 40° and 45°.

MELONS.—These require to be grown quickly, therefore close the house early in the afternoon; but as the sun has considerable power 3 P.M. will be early enough, and if the temperature rise to 90° to 95° all the better, especially where the fruits are swelling. This should be accompanied with plenty of moisture, and the plants must have sufficient moisture at the roots. As a preventive of red spider damp all available surfaces twice a day, keeping the evaporation troughs charged with liquid manure, and paint the hot-water pipes thinly with sulphur. Reduce the atmospheric moisture in houses in which the plants are in bloom, impregnating the blossoms daily, and stop one joint beyond the blossom. Attend to the stopping, tying, and thinning of the shoots as they require it, avoiding overcrowding as the greatest of evils. The linings of dung-heated pits and frames in which Melons or Cucumbers are growing will need prompt attention when the heat is declining, removing the cold material and supplying properly prepared fresh. Thin out the growths, and give air freely to plants in flower. A little more soil may be added to the hillocks or ridges of advancing plants as the roots protrude, having the soil previously warmed.

CUCUMBERS.—The plants now in full bearing will need copious supplies of tepid liquid manure; and to encourage a free growth close early, as advised for Melons, using the syringe freely at the same time. Stopping, tying, and thinning will need careful and regular attention, so as to keep up a good supply of successional bearing wood. It will be advisable to have some light shading in readiness for bright and powerful sun, so that it may be applied promptly in case of the necessity arising, and which frequently is most needed when a period of bright weather follows one of prolonged cold and dullness. The foliage must not be allowed to flag, or it will give the plants a serious check, and scorching may generally be avoided by admitting a little air early.

THE FLOWER GARDEN AND PLEASURE GROUNDS.

Pruning Roses.—The whole of this important work may well be completed at once. The experienced enthusiast may perhaps vary the pruning according to the habit of the various sorts, but this is not absolutely necessary. Prune according to the vigour of each plant, always well thinning out the centres, removing weakly growth, or if this cannot be spared cut it to the first joint and thereby secure a stronger break, keeping the lead or bush within bounds by shortening back main branches where necessary to a well-placed young shoot. For a Rose to continue vigorous the growth must be constantly starting from near the stems, and this in most cases is only effected by free annual pruning. Our plan, which rarely fails, is to cut the smallest growths either clear out or to one joint, the medium-sized growths, say of the size of a slate pencil, to two joints, and the strongest to three or four buds or joints. More blooms may sometimes result from less severe prunings, but we look beyond the current year. Growers for exhibition may be less free with the knife, as in their case they only require a few extra fine blooms for one or two seasons from the plants, and then these are either sold or thrown away. Dwarfs should be treated somewhat similarly to the standards, unless a few of the shoots are extra strong. In this case if shortened slightly and pegged down they will flower more freely, and be less likely to weaken the remainder of the bush. Pillar Roses should not be neglected if plenty of good blooms are wanted. Shorten all the side shoots according to their strength, and lay in the ripened portion of leading growths where they may be required. All Roses will be much benefited by a liberal dressing of partly decayed manure, which should only be lightly forked into the surface, and a mulching may well be given later on.

Christmas Roses.—If it is desirable to increase the stock of these popular hardy flowers it should be done by division at once. Lift the large old pieces and freely divide with a plunging fork. Replant them firmly in deeply dug rich soil. A hot dry position does not suit them, and the less they are disturbed in such positions the better. Fruit borders where they receive a little shade during the summer appears to suit them well; and as the blooms are much the best under protection, it is advisable to plant in groups so that they may be easily covered with bellglasses, handlights, or frames. Before hot weather sets in they should all be mulched with short manure or leaf soil. The most serviceable variety is that known as *Helleborus niger maximus*.

Treatment of Bedding Plants.—A considerable number of cuttings will now be rooted and seedlings raised, all of which must be kept

growing if good strong plants are desired. Some are best in pots, others in boxes. Among seedlings that are best grown in and planted out from pots are the fine-foliaged *Solanums*, such as *S. Warscewiczii*, *S. marginatum* and *S. robustum*, *Acacia lophantha*, *Grevillea robusta*, *Wigandias*, Tobacco plants, *Eucalyptus*, *Ferdinandia eminens*, *Ricinus*, *Erythrina*, *Ferula gigantea*, *Chamaepeuce*, Japanese Maize, and *Humeas*. Late in April is quite soon enough to sow the quickly-growing *Ricinus* and Maize, but all the remainder ought now to be potted singly into 3½-inch pots, be kept growing in gentle heat, and receive a shift into larger pots, say 6 inches in size, before they become stunted and root-bound. Any good light soil will suit them, and it is necessary to take so much pains with them in order to secure strong plants, which will be effective when planted out early in June. Seedling *Cannas* may be transferred into 5-inch pots and no shift given, and the old roots can safely be divided when commencing growth, and be either placed thinly in boxes of good soil or potted. *Humea elegans* is a biennial, and seedlings raised last May ought now to be shifted into 7-inch pots, kept in a greenhouse temperature, eventually hardened off, and planted out early in June. Many of the ordinary bedding plants are best in boxes, as they grow more freely, and can be transplanted more readily from boxes than from pots. This is notably the case with *Lobelias*, *Ageratums*, *Heliotropes*, *Iresines*, *Perillas*, *Violas*, *Pyrethrums*, as well as *Antirrhinums*, *Pentstemons*, *Phlox Drummondii*, *Asters*, *Stocks*, ornamental Grasses, *Godetias*, *Cineraria maritima*, *Marigolds*, *Gaillardias*, *Delphiniums*, and similar strong-rooted kinds. Those with delicate roots such as *Koniga maritima*, *Mesembryanthemums*, *Petunias*, *Sempervivums*, *Tropæolums*, as well as *Coleus Verschaffeltii*, transplant the most safely from pots. Many place the bedding *Pelargoniums* in boxes, but where an early effect is desired strong bushy plants in pots are preferable, though unless well managed these do not always become established so quickly as plants out of boxes.

Early in April is a good time for sowing in hotbeds seeds of such quick-growing plants as *Crimson* and *Chilian Beets*, *Asters*, *Stocks*, *Zinnias*, *Love-lies-bleeding*, *African* and *French Marigolds*, *Tagetes*, and ornamental Grasses. Sown earlier they are liable to be checked in growth, thus inducing premature blooming. Sow the grasses thinly, as many of them are branching in habit, and do not require pricking out. They may also be sown on the open borders.

Shrubby Calceolarias.—Where these have been wintered thickly in handlights or frames they will be useless unless bedded out where they can be protected for a time either with frames or mats. What are wanted are sturdy well-rooted plants which have experienced no serious check prior to bedding-out time. Such can be had by placing frames on a hard bottom, in these disposing a depth of about 6 inches half-decayed leaves, and on this about 4 inches of fine soil. In this place the *Calceolarias*, which ought previously to have been stopped and be breaking afresh, about 6 inches apart each way, water them in, and keep them close for a few days. Never let them become dry at the roots, eventually harden off, and use the frames for other purposes. When required they can be cut with square balls of earth and roots attached, the ready removal of which will be greatly facilitated by the hard bottom. No frames being available dig out a wide trench in the garden, prepare, and plant similarly as advised for frames, lay stakes across, and protect with mats or old pieces of carpets. Tops of these *Calceolarias* will sometimes strike in heat during the spring months, and can be grown into serviceable little plants.

THE BEE-KEEPER.

SEASONABLE NOTES ON BEES.

DURING the last fortnight we have had dry beautiful weather, and very merry have the bees been. When the air has been still and the warm sunshine has brought out the perfume from the early spring flowers the pleasant hum of the newly awakened honey gatherers has resounded on every side, and called up a kindred note of joy from the heart of the bee-keeper. We do not ever remember our bees having such an uninterrupted spell of work on the Willow blossoms, nor have the latter for many years blossomed so freely. Bee-keepers should not forget the Palm Willow, as it is called, when planting for bees. It is one of the best plants in early spring for yielding both pollen and honey, and it is ornamental and easily grown. Three years ago we bought a quantity of Willow stakes, they were tied in bundles and looked like faggots, these were driven well into the ground, about 6 feet of each stake projecting over a pond. Now these stakes have become a belt of flowering Willows, and they have given much pleasure both to the bees and to their owner.

While speaking of plants most suitable for the neighbourhood of an apiary, we would again recommend the *Ribes sanguineum* or American Flowering Currant. We have planted it largely. It is a lovely shrub, grows very quickly, forms a good hedge, and is always much sought after by the bees. A long row of these bushes is now a crimson mass of bloom, and has been for days covered by the busy workers.

Gentle feeding, carefully and continuously carried on, together with

the fine weather and the natural income, has caused breeding to be carried on apace in all our hives. Colonies are very strong, and remind us of May rather than of March. We must only hope that no long spell of cold weather will set in to retard the progress. Having once commenced feeding we must not discontinue it, until there is a certainty of a regular natural supply of food. Hives which have been regularly fed for the last two or three weeks should now be again examined.

In our last letter we explained what we considered to be the best way to proceed in overhauling a bar-frame hive; the same system should again be carried out in looking over the combs, and we would now make our first enlargement of the brood nest by reversing the position of the combs containing brood. The brood chamber in a hive is more or less spherical. We shall for the moment destroy this shape by placing the broader portions of brood on the outside of the narrow portions. In order to re-establish the natural shape of the brood nest the queen will deposit eggs in the unoccupied portions of the now inside combs, and also in the outer adjoining combs to those we brought from the inside of the brood nest; this will considerably enlarge the size of the mass of brood, and therefore require many more bees to cover it. Less bees will therefore be at liberty for outdoor work, and we must not be too eager to enlarge the nest again for another fortnight. By that time many young bees will have hatched out, and there will be more forage in the fields, and less chance of a relapse through the return of cold weather. We may then make a further enlargement by placing a frame furnished with a whole sheet of foundation in the very centre of the brood nest.

While making these inspections and enlargements of the hive we must not neglect the more important matter of seeing that the bees have plenty of food. Every day the demand will be greater and greater as young bees are hatched out. At the same time the supply from natural sources will be insufficient for some time to come to support the colony. It is from this cause that so many stocks in straw skeps die at this season of the year. The owner sees his bees at work from morn to night, he sees wild flowers in the hedgerows, and he thinks the bees are doing well, or he does not think at all. At length he finds his bees all dead, starved to death within a few weeks of the time when they would have been of great profit to him.

Owners of straw skeps should not neglect to ascertain the state of their bees at once. At the risk of repetition we will again explain how a skep should be examined. Blow a few puffs of smoke into the entrance, tap the hive, not too roughly, a few times on the top and sides; in two or three minutes the skep may be lifted gently but deliberately from its stand and turned upside down. A puff of smoke will drive the bees from any part of the combs it is wished to inspect. The centre of the hive will, in nine cases out of ten, contain the brood nest, and the store of honey, if any, will be found on the outer combs and at the top of the brood nest. The condition of the stock can be taken in at a glance, and, if no store of food be there, feeding should be immediately commenced. A good quantity—say 5 or 6 lbs.—of syrup should be rapidly given, and afterwards gentle feeding may be continued. Every skep should be made with a hole 3 or 4 inches in diameter in the centre of the crown. Over this hole a feeding-bottle can be used when necessary, and, later on, supers can be filled. Where the crown of the skep is dome-shaped, after cutting out a circular piece from the centre the top should be made level with the hole by placing a flat piece of board on it, and filling up under the board with mortar. When the mortar is dry the board can be removed and a level surface will be left upon which to place a feeding stage or supers. A rack of sectional supers can be filled over a skep as well as over the best bar-frame hive; and it is to be hoped that those who cannot see their way to substituting the latter for the old-fashioned hive, will be induced to get their surplus honey in the form most attractive and most saleable, which is undoubtedly in sections. These sections can be obtained by the dozen, the hundred, or the thousand from any dealer in hives; can be easily sent in small quantities by post, and cost about a halfpenny each. From ten to fourteen arranged in a tray and warmly covered, will be found to be most readily entered by the bees when natural conditions are favourable. And, when filled, how much more readily will a sale be found for these than for the bellglass or straw super.—P. H. P.

TRANSFERRING BEES.

I HAVE a hive of bees in a straw skep which I fed up to about 25 lbs. weight in the autumn. A few weeks ago I examined it and found it very strong both in bees and honey. I have also made a bar-frame hive as directed in your columns by Mr. Carr. Please tell me, through the *Journal of Horticulture*, if it is safe to transfer them to the bar-frame hive; if so, when, and how? The principal honey harvest here is fruit blossoms in April and May.—“A FOURTEEN-YEAR-OLD BEE-KEEPER.”

[Replying to your correspondent, I may reasonably conclude that his fourteen years' experience will enable him to form a reliable opinion as to what really constitutes a “very strong” stock of bees, or I should be

disposed to urge him to give up the idea of transferring the contents of a skep into his new hive this spring, preferring to people it with a swarm in May, so that combs as well as hive might be new the first year of his working a hive of my pattern. I claim, however, that it is the best hive extant for successfully transferring bees into from skeps.

I will pre-suppose that the stock is strong, the queen young, and the combs not more than two years old. If these conditions exist success is certain. Let the weather be fairly settled and warm in, say, the middle of April, choose a fine sunny day, and prepare for work by arranging that the entrance of the new hive shall occupy a position as near as possible to that of the skep in which the bees now are. Pieces of narrow tape each 15 inches long will be required (a knot of tailor's stay tape, costing one penny, is the best material to use). Drive the bees into an empty skep and set it where the old hive stood, brush all the stragglers off the combs with a feather, and when the skep is completely cleared of bees take it indoors at once to a warm room or greenhouse, and, remembering that it will contain hatching brood in all stages, do not leave it to become chilled or allow it to be exposed to cold wind. Set the skep bottom upwards, and with a sharp knife cut the straw on opposite sides between the centre combs down about two-thirds of its depth; cut away the skep, leaving the combs exposed so that they may be removed as required; probably about seven combs will contain brood, &c. Cut each comb out above the brood, a folded cloth covered with a piece of newspaper makes a soft bed for it to lie on, and does not injure the brood; lay the top bar of a frame with its under side close to the upper edge of the comb, and with a pocket knife cut round the inside of the frame, so that when the superfluous parts are removed the comb will fit closely into the frame. A couple of tapes tied round the outside of the frame will keep the comb firm. As each comb of brood is fitted into a frame set it in the “spare frame box” (which may be placed in front of the fire for warmth). About seven frames will probably hold all the combs which contain brood, eggs, &c., and one additional comb may be given with honey and pollen.

Should the brood in any comb extend below the depth of the frame it must be cut neatly through, and two of such narrow pieces fitted together will fill another frame. The bees in the hive will thus be confined to eight combs, and if the stock is a good one they will fill up the space completely, with no risk of chilling brood.

Carry the eight frames in the spare frame box and set them in position at one end of the hive, close up with the divider, and place the empty spare frame box on the top of the frames. Now bring the bees in the skep, and with a smart rap knock them out on the top of the frames; the empty box will keep them from running over the sides, and they will soon take possession of their brood combs.

Put plenty of covering to keep them warm and feed regularly. Contract the entrance to less than an inch, using one of the side entrances, not the centre one. As the bees hatch out and require more room give frames of foundation, but as the main honey harvest comes in it will be better to give a crate of sections before the bees have filled all the frames in the body box. The advantage will then be found of being able to let them add to the brood combs without disturbing the crate of sections; but the zinc excluder must be used to keep the queen below.—W. B. C., *Higher Bebington.*]

TRADE CATALOGUE RECEIVED.

J. Epps, Vauxhall Station and Ringwood, Hants.—*Price List of Peats Leaf Mould, Loam, and Sand.*

* * All correspondence should be directed either to “THE EDITOR” or to “THE PUBLISHER.” Letters addressed to Dr. Hogg or members of the staff often remain unopened unavoidably. We request that no one will write privately to any of our correspondents, as doing so subjects them to unjustifiable trouble and expense.

Correspondents should not mix up on the same sheet questions relating to Gardening and those on Bee subjects, and should never send more than two or three questions at once. All articles intended for insertion should be written on one side of the paper only. We cannot reply to questions through the post, and we do not undertake to return rejected communications.

Books (W. Williams).—You can obtain all the particulars you require by writing to the address that was given on page 254 last week. We do not supply the work in question.

Inquiry on Vines (*J. M., Northampton*).—Your inquiry never reached our hands. If you will send full particulars of the condition of the Vines on which you need information your letter shall have our best attention.

Stamps for Numbers (*H. S.*).—You have not sent stamps for postage. If you send 3d. more, what you want shall be forwarded; but you will perceive that your name and full postal address are necessary for this, and these you have accidentally omitted. Your question about Vines will be answered next week.

Winter-flowering Heaths (*A Young Head Gardener*).—Undoubtedly these rank amongst the most ornamental and admired of flowering plants during autumn, winter, and early spring, and they ought to be more extensively grown. We shall publish an article on their culture in an early issue that will be more serviceable to you than a brief reply in this column. Many persons fail to grow these plants well, some by want by experience, others by lack of the requisite accommodation.

Vines Flagging (*A. G.*).—You do not state how far your Vines are advanced, and unless they are in flower the temperature is 5° too high. You have probably used too much fire heat from the commencement, and kept the house too close. This, with a period of dull weather, would result in flimsy foliage that could not endure a sudden outburst of sun. As the roots are in an outside border they can scarcely be dry. Lower the temperature a few degrees, avoid a close moist atmosphere, leave the top lights slightly open all night, admitting more air immediately the thermometer indicates an increase of temperature in the morning, and you may expect more substance in the leaves, better enabling them to endure the sun. If they continue to flag sprinkle the glass with whitewash applied with the syringe; but only as the lesser of two evils, scorching being the greater. Are the roots active and working in good soil?

Heating Vineries (*C. H., Belgium*).—The maximum temperature you will need in a late vinery will be 70° to 75° by artificial means, and to secure that you will need six rows of 4-inch pipes along the front of the house, or three flows and the same number of return pipes. The pipes must be so placed that they are above the border, and would be best disposed on the flat, so as to extend over a considerable part of the area, and thereby diffuse the heat more evenly. There ought to be a clear space of a yard between the pipes and the front wall, so as to admit of the Vines being planted along the front inside the house. Four rows of 4-inch pipes—that is, two flows and corresponding returns, will be sufficient heating power for the early vineries. You do not give any position for the boiler, but we presume it would be fixed in the coach house at the back of the late house, through into that house at the end next the early house, and then branch from it to the early vinery, the pipes being taken in a covered flue or drain along the back pathway of the late house to the early house in front of the gardener's rooms. You will need valves on all the flow and return pipes, so that the houses can be heated separately or together as required. Ventilators in the back wall would not suffice, as we fail to see where the ventilation is to come from: there really is no means of the heated air passing away and being replaced by fresh. The chief ventilators should be in the roof, lights running the whole length of each house and made to open by crank and lever movement little or much as required. For the late house the opening lights ought to be 3 feet wide or down the roof, whilst for the early houses 2 feet wide would be suitable.

Vines (*A Lady*).—If your Vines are healthy and the roots are plentiful near the surface of the border, the compost of which is good, the bunches you describe will develop, and weigh, perhaps, a pound each, or at least the best of them ought to do so under good management. The temperature of your house is 5° too high by fire heat, but the sun temperature of 85° is right. The late varieties are rather slow in starting, but with a genial atmosphere they will soon commence growing at the present temperature. When the bunches are visible the heat may be raised 5°; and if you increase that a few degrees when flowering, again similarly when the berries commence swelling after stoning, allowing a proportionate increase of sun heat, the Grapes will be ripe in September.

Tomatoes (*Idem*).—A compost of two parts turfy loam, one of decayed manure, and a sixth part of pulverised bones will be suitable for Tomatoes, and you may drain the pots as you propose. You would probably find Mr. Iggulden's manual "The Tomato" useful, which can be had post free from our office in return for 1s. 1d. in postage stamps. It gives all the details of culture both in pots, frames, and the open air.

Marechal Niel Rose Leaves Withering (*A. S. D.*).—It is not unusual for a number of the first formed small leaves to wither as the larger, later, and better foliage expands, and the growth of the Rose advances towards the flowering stage; several leaves that have remained on the stems since last year also wither in the spring. There are still signs of scorching on the leaves sent that would seem to indicate some error in ventilation. Syringing too late in the afternoon and deferring the opening of the ventilators too long in the morning would contribute to the withering of the leaves, so would insufficient supplies of water at the roots. You do not state the size of the plant; unless it is very small the quantity of water you give is not half sufficient. Possibly it is in this respect you err, and liquid manure also may be needed. After writing the above your letter was destroyed, and as your address cannot be remembered you will perhaps oblige with it again, and what you want shall be sent; if at the same time you state the space your Rose occupies and the nature of the soil, with the size of the border, we may perhaps be able to give you further advice on the subject.

Marechal Niel Rose (*G. F. M.*).—It is almost impossible for us to fully comprehend the condition of a plant from a general description of it in a short letter. The plant, judging from the specimens sent, is certainly in a debilitated state, and has not strength for developing the flowers; it is, therefore, overcropped, few as the blooms may be. As to the soundness of our advice on cutting-back the growths, we need no better testimony than is embodied in a communication from Mr. Divers in another column. Nowhere is this grand Rose grown better than at Burghley, hundreds of blooms of exhibition quality being cut from one plant, the leaves of which are at the least four times the size of those you have sent. But cutting-down alone is not sufficient for producing vigorous growth. The roots of the plant must

be strong and actively working in good soil, and the stock must be sound. Perhaps the stock of your tree is faulty in some respect. Is it cracked or cankered? Again, the tree may be old and worn out, as this Rose does not usually continue vigorous for many years on the Briar. There are exceptions, we know, but the rule we have stated. The border you mention is abundantly large, but what of the soil? It may be sour or inert, or possibly it is or has been dry at the bottom. If the plant is not old and the stock is sound we have no doubt we could improve the condition of the Rose. As it appears that something more than mulching is needed we should dig out most of the old soil, keeping the roots moist during the process, and the foliage too, shading it also if needed to prevent flagging. We should then surround the roots with turfy loam, with a seventh of decayed manure mixed with it, and a liberal quantity of wood ashes if available, or a sprinkling of bonemeal, say two quarts to a bushel of soil. We should also shorten-back the growths to good buds in the young wood, syringe the plant, and keep it as warm as possible, then expect fresh growth to start that would gather strength during the season and produce far better foliage than is produced now, and eventually better flowers. You will perceive we are very willing to assist you, but feel a desire to know something more of the character of the plant to enable us to do so effectively and to our satisfaction.

Moss Litter for Mushroom Beds (*J. H. B., Sunderland*).—Gardeners who contribute to the press, or whose success in culture is recorded therein, are often troubled with so many letters that they are unable to answer them; also by want of thought on the part of seekers for information are taxed with postage, if they do reply, that ought not to be imposed. If you did not enclose a stamped directed envelope to the gardener you name he was quite justified in not acknowledging the receipt of your letter. Moss litter after being used in stables is an excellent medium for growing Mushrooms. We have seen highly productive beds that were made with this material, not outdoors, but in a close shed. Mr. Walker of Sheffield grew his Mushrooms in boxes under cover, and they were referred to as follows by a correspondent in December, 1882:—"Mr. Walker made up some beds with moss litter, which have succeeded beyond his expectations. He says he has never before had beds which have been so quick in coming into bearing or so lastingly productive. He commenced gathering Mushrooms in five weeks from the making-up of the beds, and when I saw them he had been gathering from them every day for five weeks, and the beds then were quite covered with fine Mushrooms, which are very thick and solid. He also showed me a box which by way of experiment he had filled with moss which had not been used in the stables, but which he had saturated with stable drainage from a tank where it is collected. This upon being made up into the box heated very strongly, so that he had to wait a number of days for the heat to subside before spawning, but when I first saw it the spawn had run through it and Mushrooms were appearing apparently as thickly and as freely as upon the other beds. On a subsequent examination there was no doubt the experiment was a great success, as the box was crowded with splendid Mushrooms." If you desire further details on growing Mushrooms in moss litter you will find them on page 442, vol. vi., of the Journal, the issue of May 31st, 1883. If you do not possess that number we think it can be supplied by the publisher on receipt of 3½d. in postage stamps and naming the date we have given.

Vines Dying (*G. M.*).—We sympathise with you very much in the loss of your Vines. It is, indeed, a great disappointment to see them die one after another in the way you mention. We are more surprised at the old than the young Vines dying, assuming they are not attacked with the phylloxera. Whether they are or not it is impossible to determine without a close examination of a portion of the old roots, and especially the young fibres. You say nothing about the soil. Are you sure it is suitable? The protection you have given is quite sufficient. We are not at all surprised to hear of the collapse of young Vines planted in an outside border, and the whole length of the rod retained and started into growth in February. By that treatment the sap is drawn out of the stems before a sufficient number of roots are produced for continuing the supply. One of your Vines affords evidence that the root-action was too feeble for the length of cane, as when this was cut down to the ground it commenced growing. Making a border of good soil 3 or 4 feet wide up to the side of the house, and planting canes shortened to 2 or 3 feet, would with good attention result in healthy rods. It does not do, however, to shorten the canes in spring, and any that may be planted now should have the buds removed from the upper half of them, thus concentrating the force of the roots on the buds below. A narrow border is as good as a wide one the first year, and it can be increased in width as required. We presume you have examined the stems of the Vines and satisfied yourself that they have not been injured by rats or mice. We have known several Vines killed by these destructive rodents gnawing the stems and cutting off the supply of food from the roots. If we can help you further we shall be glad to do so.

Fungus in Vinery (*S. E.*).—We are sorry to inform you that your Vines are infested with fungus, the bark being thickly covered with it in a manner which we have not previously seen, and it is also unfortunately present on the roots. A portion of the mulching material is also permeated with fungus, including the mycelium of the Mushroom. It is in all probability with this mulching that the fungus has been introduced. It may be cleansed from the rods easily, and as the roots may not be seriously infested, as those before us are not, the Vines may possibly recover. At once remove the loose bark carefully and burn it, then thoroughly wash the rods with a mixture of sulphur and water. The mixture will be more easily effected if a few handfuls of sulphur are tied up in a piece of canvas and soaked for a time in hot water; then rub it well with the hand and mix in cold water to the consistency of cream. Apply this to the rods, rubbing it well into the interstices of the bark with a brush. A toothbrush will be useful for working round the spurs. If this work is well done the fungus on the rods will be destroyed. Next remove all the mulching from the borders with a portion of soil, and give a good dressing of freshly slaked lime, spreading it on to the depth of half an inch and pointing it into the surface, then giving a heavy watering with water at the temperature of 100°. If you can readily procure some ammoniacal liquor from gasworks, and add one gallon to five of the water, it will act both as a destroyer of fungus and a manure to the Vines. Although the border is not dry, this watering will do no harm but good, as it will warm the border, thus inciting more root-action, and check the

spreading of the fungus. You will do well also to paint the hot-water pipes with the sulphur mixture, not, however, having them very hot when it is applied. Still they may be heated. Raise the temperature of the house 5° by fire heat and maintain a buoyant atmosphere, anything approaching to mugginess to be carefully avoided. The top ventilators should be left slightly open all night and further opened shortly after the sun reaches the house in the morning, and do not close early in the afternoon in the usual manner for promoting a humid atmosphere. We are not without hope that under the treatment suggested the Vines will improve. Your letter is so explicit that we fail to see you would derive any advantage from a personal interview. We shall be glad to have a further report in the course of a month on the condition of the Vines.

Names of Plants (Youth).—1, *Erica carnea*; 2, *Lithospermum prostratum*; 3, *Omphalodes verna*. (C. W.).—We do not recognise the varieties, one of the blooms of which was quite withered and the others injured in transit; nor do we undertake, as we have many times stated, to name Camellias or other varieties of florists' flowers that originated from seed. They are far too numerous, and many of them too closely resembling each other, for anyone to do so without actual comparison with others in a large collection.

Smoking Bees (D. Smith).—"P. H. P." uses an ordinary bellows smoker, and says you cannot do better than get "Clark's American Smoker," price 3s. This will burn almost anything, and keep alight for hours. Rotten wood answers well, but rags, dry sawdust, brown paper, &c., answer equally well. This smoker can be obtained from Messrs. Neighbour, 149, Regent Street, London.

COVENT GARDEN MARKET.—APRIL 2ND.

A FEW samples of new Grapes to hand, but with the gloom over business and a good supply of old, they meet with a cold reception. Prices generally barely maintained. Large supplies of vegetables.

MILDEW IN WHEAT.

(Continued from page 256.)

BEFORE entering upon the disposal or destruction of the germs or spores of this mischievous fungus we must refer to some of the most prominent forms of its species, and their time and mode of attack, together with a statement of those districts wherein it is most prevalent, also by looking back and noting those years when it has proved particularly injurious. The conditions under which the disease is developed to the greatest degree must not be omitted, such as the situation of the farm or fields, with the soil and climate which favour or resist the disease. We must also consider how previous cultivation may inadvertently favour the disease, or may by judicious and special management evade loss from it. The sort of Wheat, the period of sowing, and the quantity of seed used per acre must be thought of. The period of harvest, the flowering period, and the date of first observation of the disease must, with other general observations, be noticed with a practical minuteness so essential in enabling us to combat the disease, and to some extent to evade it by anticipatory management in various ways.

One of the most singular means by which this fungus may be

unwittingly propagated—we allude more particularly to a special means of propagating or reviving the real and fatal mildew—is related in Mr. Little's essay before referred to. This states "that the form in which the spores (called Teleuto spores, or rest spores) are capable of lying dormant and retaining their vitality. Starting from this point—that is, with the blackened straw of the previous year, we find that in the spring the Teleuto spores are quickened into life, and from them are produced another kind of spores (Promycelium spores), which are said to be unable to retain life and bear fruit unless they can meet with a Barberry tree or bush. Having settled upon a leaf of one of these shrubs the spore bores into the interior, and there develops into mycelium, which in the course of about eighty days produces rusty patches both on the upper and under sides of the Barberry leaf. From these spots of rust two different kinds of spore are shed—*Æcidium* spores from the under, *Spermagonia* from the upper side of the leaf, and it is supposed by Mr. Plowright they are of different sexes, the smaller spores or *Spermagonia* playing the part of the male. *Æcidium* spores (perhaps fertilised by the *Spermagonia*) are distributed in the air in incalculable numbers, and those which fall on plants adapted to fulfil the office of host plants, germinate under favourable atmospheric conditions—that is to say, in damp weather, and throw out a germ tube, which enters the host plant through one of its stomata or breathing pores. Having effected an entrance, mycelium is again developed in the tissue of the plant (Wheat or Grass), and the fungus has now obtained possession of a home in which it can complete its life cycle. In the course of ten or twelve days *Uredo* spores are produced on the outside of the leaf. These are distributed, and germinate and reproduce their kind. The reproduction of *Uredo* is repeated generation after generation until the host plant approaches maturity, when the mycelium throws out Teleuto spores or mildew, and the life cycle is completed."

In the foregoing quotation we recognise the identity of the fungus which produces Barberry rust with that which afterwards produces a rust on Wheat and eventually mildew, which is assumed as undisputably proved. Still it is disputed by some authorities, although we know a considerable number of practical farmers who are believers in the theory from having suffered serious losses from the mildew having spread from the Barberry bushes. To prove this we were, about twenty-five years ago, invited by a farmer in North Hampshire to visit his farm, on the estate of the late Sir William Heathcote, Bart., to view the blight extending over a large portion of a field of Wheat of about 12 acres. The rust was upon the Barberry bush in the hedge on the north-west side of the field, and the blight, which proved to be mildew, started directly from the Barberry bush, and gradually spread out like a fan opened, and upon close examination we found the straw discoloured by patches of a black and brown colour. This was about the last week in June, the Wheat previously looked well, with a bulk of straw equal to a crop of thirty bushels per acre in a favourable season. We visited this farm again at Michaelmas, and found that the whole of this crop had been cut and harvested as loose corn, and given to pigs for food in the farmyard, as it afforded only skeleton corn, which could neither be threshed nor separated from the husk, as in the ordinary practice of threshing.

Before seeing the above-noted result we were as sceptical as many others were, or may be now, as to this shrub being the medium of introduction of so destructive a mildew. Even in this or other cases it would not have succeeded if the weather had not been dark with drizzling rain, and it is most probably in this way that the theory is discredited, because the same results might not, and probably would not have occurred of a bright and sunny season. We can, however, well remember instances when the Wheat crop appeared safe from blight of any description, yet in fine hot weather when the harvest has been proceeding with every prospect of success, the grain became shrivelled, and in a portion of the same field the injury to the latest cutting was very serious both in quality and weight per bushel. Such sudden mishaps as this are by no means frequent, and this is fortunate, for it is far beyond our control, and can only be successfully guarded against by the early cutting of the crop, thus preventing any latent disease or partial mildew from proceeding to disaster through delay in the harvest field, which also, quite irrespective of mildew or other disease, seriously injures the prospects of the farmer should bad weather set in, as was the case last year in nearly all the latest districts of the kingdom. It must therefore be admitted that the mildew in Wheat will be credited with having taught a lesson—the advantages of early cutting of the Wheat, and especially in those cases where the crop is laid or lodged through the weight and bulk of the crop.

There are some interesting statements in Mr. Little's essay afforded by correspondence with a large number of practical farmers in various districts of the kingdom, and it appears from these reports that the mildew years did not seriously affect the whole kingdom in the same seasons, no doubt owing to the difference of soil and

climate. It also appears that several correspondents seem never to have had any serious experience of it in any season. These fortunate correspondents and farmers hail from Berks, Devon, Hereford, Herts, Hants, Kent, Leicester, Lincoln, Norfolk, and Sussex. On the other hand, representatives of Beds, Berks, Bucks, Cambs, Cornwall, Devon, Dorset, Hants, Huntingdon, Kent, Lincoln, Norfolk, Somerset, Sussex, and Wilts seem to have suffered seriously. In these returns the worst districts outside of the Fen country come from the neighbourhood of Hythe in Kent, Hampshire, the Downs of Wilts and Berks, the lowlands of Somerset, from North Devon, North Cornwall, and the Wolds of Lincolnshire. It would seem that next to low-lying lands those of great elevation and exposed situation suffer most, while the slightly elevated lands are the happy medium. Undoubtedly these facts induce the conclusion that mists and a saturated atmosphere are the chief conditions under which the mildew spores germinate most freely, and which are more common in the case of the vales and on the heights than in the middle zone between the two, and the fact of mildew being more felt in these situations seems to support not only the conclusions of Mr. Carruthers, but also our own observations and experience upon the subject. With respect to "mildew years" we hold that they cannot be defined by any lists of counties or districts as above stated, but that there is rarely or perhaps never a season wherein mildew is not injurious in some of the districts more than others. If, however, we were to attempt to decide that certain districts are more liable to suffer more particularly we should name the Fen districts of the eastern counties.

In referring to the subject of the destruction of the mildew germs it would seem as before stated by the scientific notice of the subject that nothing but fire will destroy them, in which case we must endeavour to evade them, for we cannot advise the destruction of our best medium straw for manure-making by fire. Yet the straw may be converted as usual into strong ammoniacal manure by the consumption of cake and roots by cattle and sheep, and having this to depend upon for the future purpose of the growths of farm crops. It is extremely important to consider how in conjunction with feeding our cattle, and the consumption of the green crops and roots of the farm, we can avoid the serious injury which it appears from all the evidence adduced by scientific men, and not disputed by practical farmers, and this we must endeavour to explain, together with other important considerations.

(To be continued.)

WORK ON THE HOME FARM.

Horse Labour.—Horses are fully engaged in the work peculiar to the time of year. Amongst other work the meadows intended to be mown for hay or ensilage should now be rolled with the heavy ring roller before the land becomes too hard, in order that stones may be pressed into the soil, and the same work be done on park lands, as also the Clovers and field grasses if not previously rolled. There is, however, no pressing necessity for rolling the pastures as compared with the tillage of the land, which is best done in fine weather, whereas rolling the pastures may stand over and be done after a timely rain. Where the land is intended for a fallow and green manuring combined it is time to sow the Mustard for the first sowing, and as the most approved plan is to grow three crops in succession, to be ploughed in at varying depths—that is, deeper on each successive seeding, and in this way the fallow is made—that is, the couch and weeds are buried under with the Mustard crop, all contributing to the manuring of the land, and so preparing it for a full crop of Wheat. The effect of fallowing and the last crop of Mustard ploughed in early during the month of August or September is important by giving the land time to settle before sowing, because three bulky crops of Mustard, each of which will be in general 3 feet high, but notwithstanding the land is pressed with the ring presser as fast as ploughed each time and the seed sown, yet the bulk of green produce serves to lighten the land and make it hollow and unkind for Wheat, unless the last ploughing, rolling is done in good time, so that it may settle by the effect of rain, and get stale and mellow through successive changes of the atmosphere, for at least two months before the seed is sown or drilled, the latter being best; for unless it is drilled wide apart, say 10 or 12 inches, upon the best strong or loamy soils, it will be likely to run into an excessive bulk of straw sufficient to injure the yield. It must be remembered that such crops of green foliage when well buried in the soil is not only quite enough to enrich the land for a bulky crop of Wheat, but also equal to the requirements of the next succeeding crop without any further manure being applied, and ready at the earliest period for seeding with either Barley or Oats. Sheep should now be finished feeding with root crops, so that the land intended for Oats or drage may be sown, as it is now too late for Barley if a malting sample is required, after which the sheep on the vale farms may be sold, and those on the hill-breeding stock farms may be put upon the water meadows, with a change on to Rye on the arable land, which crop is this year exceedingly forward, as we have seen the stems of Rye a few days ago 3 feet long.

Hand Labour.—Work is now plentiful. Laying out yard manure for the Mangold crop is now going on, also for Potatoes if not yet done, the spreading of which will engage some men for some days. Preparations should now be made for cutting and barking or peeling Oak trees, for on some estates large falls of timber are about to take place, and in some

instances we fear it is an enforced matter in consequence of a reduction on the rent roll through the difficulty of managing farms on hand, which on various estates are numerous, and which, although they may be laid into permanent pasture, yet this is an expensive matter, as well as the outlay for cattle for stocking the pastures. It is, therefore, a matter of the highest importance that the home farms throughout the kingdom should be managed by men of great experience, of energy sufficient to enable them to encounter the various changes which are recommended for the successful conduct of the farms in hand.

Live Stock.—The management of swine is now attracting more attention than of late, and we have no doubt that a change is at hand which will lessen the number kept and bred on the farm of the smaller breeds, more particularly those which only make light weights with a too large proportion of fat, and will, as a necessary precaution, give way to the larger breeds to enable the farmers to obtain a larger commercial profit upon their transactions in swine-breeding. Upon this point, after a long experience, we recommend that the two breeds which should be kept are the Berkshires and the large white Yorkshire; and we further believe that the cross-bred swine as obtained by mating the Berkshire sow with the Yorkshire boar is more profitable than either of these pure breeds if kept solely for profit on the farm by breeding and feeding for bacon hogs. Yet where either sort is raised as a speciality, having a good name and repute, and in the hands of careful and experienced breeders, young animals of both sexes may be sold at remunerating prices. It is of the utmost consequence to the approvers of either breed to be sure of obtaining well-bred stock. Breeding for sale of such stock or for crossing must always insure a free sale, and whether the demand is for crossing or pure breeding, yet the final object is the same—that of being enabled to obtain the greatest number of young in a farrow, and also the greatest weight for age to meet all demands, and likewise to insure the largest proportion of lean to the fat after good feeding, suitable for every branch of the trade requirements in bacon and pork. The deadlock at present existing in the legislation for the purpose of banishing and keeping out of the country the foot-and-mouth disease in cattle is much to be deplored, especially at this time when so much land has been laid into grass, and the popular opinion being strongly in favour of live stock production in preference to the growth of corn, although it still influences many farmers in pursuit of profit. It must be admitted that legislation has not yet given the dairy farmer and cattle grazier any security against diseases in the purchase or even in the breeding of cattle, and it is from this circumstance that thousands of young men who would invest in dairy farming and the breeding of cattle generally are deterred from so doing, and many are taking their capital abroad, where there is more security, and the breeding of cattle less speculative. In fact we cannot see at the present time any hope of the matter being arranged, which is now in controversy, so as to give reasonable hope of the home farmer being enabled to stock his pastures with a prospect of profit.

OUR LETTER BOX.

Kohl Rabi (W. J.).—Mr. William Bennett of Cambridge states that his practice "is not to drill the seed before the 1st of May. We seldom use more than 2 lbs. of seed per acre drilled on ridges 27 inches apart, thinning the plants in the rows to about 16 inches apart. After ridging the land as if for Swedish Turnips we lay out in the furrows 10 tons of farmyard dung, and spread about 5 cwt. per acre of superphosphate, rape-cake, &c. The ridges are then reversed, which buries the manure in the centre of the ridges. By this method of cultivation on land worth 30s. per acre to rent, we usually grow from 25 to 30 tons per acre of excellent bulbs, besides the greens, which are first-rate food; and where a dairy is kept they are of no small value to the milking cows, as they give no unpleasant flavour to the butter."

REMARKS

23rd.—Solar halo, 8.30 to 9 A.M.; fine all day.
24th.—Fine throughout, with warm sun.
25th.—Fair, but colder, with dry parching wind.
26th.—Dull, but fair.
27th.—Overcast nearly all day, dry and cool.
28th.—Another overcast dry day.
29th.—Dry and fair with occasional sunshine, and starlight evening.
Barometer high, temperature much lower than in previous weeks, and very near the average. Air often very dry, and no rain.—G. J. SYMONS.

AMARYLLISES.

HYBRIDISING has produced wonderful effects in many families of the vegetable world, both ornamental and useful, and every year the importance of the art is becoming more fully recognised, as fresh proofs are afforded of the extent to which many plants can be improved by its aid. In the majority of cases it is no longer conducted in a haphazard manner, with the hope that fortune may favour the cultivator's efforts with something novel or good, but the hybridiser starts upon his task with a distinct conception of some desirable result, and adopts what he considers the best means of accomplishing success. He may need a large share of patience in his work, but well-directed and sustained efforts have ultimately in innumerable instances caused his greatest hopes to be realised. Examples of this are afforded by most of the genera of popular plants grown for decorative purposes, and the progress of several has been occasionally traced in these pages; but as an example of special importance and interest at the present time the Amaryllises or Hippeastrums are worthy of some detailed reference.

Scores of visitors have, during the last few weeks, admired Messrs. Veitch's grand collection of Amaryllises at Chelsea, but beyond the initiated horticulturists few perhaps of those who observed the great size, symmetrical form, and brilliant colours of the hundreds of flowers there displayed had any idea of the time, care, skill, and perseverance required to produce such glorious results. Probably many would attribute the superiority to better methods of cultivation; but though this has much to do with the matter, it would be impossible for the most skilful grower to render varieties such as are even now seen at exhibitions from amateurs in any degree as handsome as the improved forms produced by crossing and hybridising. For a long time the great object of the Amaryllis lover was to improve its form; the petals were too narrow, and the flower too thin to please a florist's eye. Flowers of larger size, with broad rounded petals, were soon obtained, but with this advance in one direction there was a corresponding loss in another—namely, the colours decreased in brilliancy almost in the same ratio as the size and form improved. Having, however, gained the finer flowers the next efforts were directed to restoring or increasing the richness and brilliancy of colour. There, again, success waited upon the improver's exertions, and in consequence varieties have now been produced which are so near perfection in all the leading qualities so anxiously striven for that there appears to be little room for farther advancement. There have been many workers in this cause, but the greatest success in recent years has been achieved by Messrs. J. Veitch & Sons and Mr. B. S. Williams, who have sent into commerce varieties of standard excellence, those from Holloway being unexcelled in brightness of colour; the Chelsea varieties unequalled in form and size, while in some cases, as already noted, a combination of

the brightest colours with the most handsome forms has been effected.

Comparing the varieties at present grown in the best collections with the early forms of the parent species we see at a glance how great has been the progress. For instance, *Amaryllis equestris*, the principal progenitor of the race, was in its original form comparatively insignificant. Turning to the "Botanical Magazine," plate 305, published in the year 1795, we find a figure of a flower 3 or 4 inches in diameter, with petals scarcely an inch in breadth and acutely pointed, but of a fairly bright shade of scarlet and white at the base. This was the type first known, and which was introduced by Dr. W. Pitcairn to the Royal Gardens, Kew, many years previously. Some years subsequently a greatly improved variety appeared, said to be from Guadaloupe, which was figured under the name of *A. equestris major* in the "Botanical Register," 1817. This had flowers $6\frac{1}{2}$ inches across, the petals neatly formed, 2 inches in diameter, and similarly coloured to the species. In shape and size this was an enormous advance, and was a most welcome addition to the small number then known, besides affording a valuable foundation for further improvements.

Another early-known species, the Mexican Lily, *Amaryllis reginae* or *Hippeastrum regium*, is somewhat of the same style as *A. equestris*, but the flower contained rather more of a crimson shade with a lighter stripe in the centre of the petals and not confined to the base, as in the one previously mentioned. It is said to have first flowered in Mr. Fairchild's garden at Hoxton in 1728, and was then called *Lilium reginae*, "because it was in its best condition early in March, about the time of the Queen's birthday." The influence of this species may be traced in the varieties at the present time, for with the aid of another species, *A. vittata*, the reputedly first hybrid, *A. Johnstoni*, was obtained, which from repeated crossing with other species or varieties has yielded a numerous progeny.

Amaryllis vittata is even in its primitive state a beautiful plant, and perhaps less improvement has been effected in this type than in any other except in the size of the flower. An excellent figure was given in the "Botanical Magazine" for 1790, plate 129, which represents the flower as 3 to 4 inches long, 3 inches in diameter at the mouth, with petals 1 inch or less in breadth, white, with two rich rosy stripes down each, and a neatly waved margin. Varieties that have evidently descended from this are traceable in most collections; but though the flowers are much larger than those in the engraving named, the body colour is seldom so pure or the stripes so rich.

A. solandraeflora, from Cayenne, has assisted in a slight degree in producing the present race of Amaryllises, but not to the same extent as the others named. The flower is remarkable for the great length of the tube, which is often as much as 9 inches long, funnel-shaped, with a slightly expanded mouth, creamy white in the type; but in a variety termed *vittata*, represented in the "Botanical Register" in 1825, the petals have a rose-coloured central band and tube rich crimson.

About 1819 a species was introduced from Brazil by Mr. Griffin of South Lambeth. This was named *Amaryllis aulica*, which has played an important part in the improvement of the family, though the original form scarcely merited the title of "a splendid novelty" as it was then described. The flowers are very loose but large, 6 to 7 inches in diameter; the petals 1 to 2 inches across, of a rich crimson colour and greenish at the base. It is of strong growth, and has probably been useful in rendering some of the hybrids more vigorous if it has done nothing else.

Amongst the curiosities *A. psittacina* is very notable. It is from Rio Janeiro, with greenish flowers of good form; the petals rounded with a margin of deep red, which runs into the substance of the flower in the form of heavy veins, having a peculiar appearance. *A. pardina* is of much later introduc-

tion, dating from 1867. It has neatly formed orange-tinted flowers, but has not produced very remarkable results.

By far the most important of all is *A. Leopoldi*, which Mr. Pearce introduced from Peru for Messrs. Veitch, and which was shown at Kensington in 1869 at the time of King Leopold's visit, and was thence honoured with its present name. This is a magnificent species with massive flowers, broad rounded petals, and of a distinct colouring; the tips of the petals white, the centre crimson, and the base greenish, being, moreover, of very strong habit and easy culture. It was a most valuable acquisition to the hybridists, and advantage was taken of its character in every possible way. For a time, however, this had a rather injurious effect, for its prepotency became apparent in nearly all the varieties, and there was some danger of the dazzling scarlet shades being almost lost. That difficulty was soon overcome, and then it was found how much had been effected by the transfusion of fresh blood from *A. Leopoldi*. The whole race of *Amaryllises* were in a measure remodelled, and the result is seen in the magnificent series of varieties now in cultivation. An excellent example of an improved variety of the *Leopoldi* type is shown in the woodcut (fig. 70, page 287), which is one of Messrs. Veitch's novelties for the present year, and is distinguished by its even form, bright crimson-scarlet colour, and white tips. It bears the classical name of Mars, and is certain to command the favour of all who wish to grow the best forms.

The foregoing is but a brief review of the species that have been concerned in the progress of *Amaryllises*, and much more could be added in reference to the gradual steps by which the advance was made, by tracing the hybrids first obtained and their part in subsequent crossing. Sufficient has, however, been said to give some idea of the work and thought that have been brought to bear on the production of the *Amaryllises* so much admired.

RHUBARB.

OF the confusion which exists in the nomenclature of Rhubarb the trial at Chiswick affords conclusive proof. A sense of this confusion, and a desire to see for myself which were the best sorts to grow, induced me to procure as many of the so-called best varieties as I could and to plant them side by side, so that the trial might be as fair as possible and the results really useful. Well, the results are before me, and I shall doubtless derive much benefit from them; but uncertainty about the correctness of some of the names prevents me making them so fully useful to readers of the Journal as I could wish. For example, the plant bearing the name of Myatt's Linnaeus was quite ten days earlier than any of the others; but that is its only merit, for it is deficient both in flavour and colour. Mitchell's Royal Albert came next, and is good both in flavour and colour. Hawke's Champagne, which I believe is true to name, followed, and it combines the high qualities of earliness, flavour, and colour better than any other. Kershaw's Paragon is excellent in flavour and high-coloured; and of others Baldry's Scarlet Defiance may be mentioned for its superior flavour, Johnson's St. Martin and Salt's Crimson for colour, and Stott's Monarch for its lateness and extraordinary size, which render it so distinct as to be easily recognised.

The best variety of Early Red or Royal Albert, with Hawke's Champagne for a main crop, both for forcing and the open garden, and Stott's Monarch for a late supply, will probably prove the best selection for general culture. In making a selection, however, it should not be forgotten that Rhubarb is at its best when quite young and tender, and to retain its full flavour it should never be peeled, but the stalks should be carefully rubbed with a dry cloth before being cut up.—EDWARD LUCKHURST.

THE BEST ADIANTUMS.

(Continued from page 184.)

GREENHOUSE SPECIES.

A. affine (Willd.).—A very handsome Fern, producing large deltoid fronds, bi or tri-pinnately divided, the terminal pinnæ much the largest. The pinnules and final divisions are half an inch or more long, crenated at the margins, of a deep glistening green colour. The stipes and rachises are black and glossy, while the pinnæ are numerous and overlap each other freely. It

is a very useful Fern, the fronds being serviceable for bouquets. It grows freely in a shallow pan or planted on the rockery, its rhizomes creeping close to or quite upon the surface.

A. assimile (Swartz.).—This is a very lovely species with drooping tripinnate fronds, growing from 9 to 15 inches long the small ultimate divisions roundish, with entire margins, of delicate pale green colour, in a young state tinged with pin. Admirably suited for market culture or the adornment of rocky ledge. It constitutes one of the prettiest cool house Ferns, and when cut and mixed with flowers the fronds present a charming appearance. If plants are grown in a low temperature they become moderately firm and will stand exposure well. It is found in Australia, New Zealand, and Tasmania, and has been grown in our gardens many years, but is much more seldom seen than should be the case with such an elegant Fern.

A. Capillus-Veneris daphnites.—Of all the forms of our native Maidenhair I think this is the handsomest for cultivation in the cool house. The fronds grow from 6 to 12 inches high. Numerous segments being united, form broad crested extremities to each of the pinnæ; and the apex of the fronds, which is of a distinct dullish green colour, with the cristation rendering the plant distinct from all others. *A. C.-V. magnificum* is also a very fine form, producing large arching fronds with broad imbricated pinnules, with finely fringed margins. These are two most lovely Ferns, and all cool house collections should include them either on the rockery or in pots.

A. colpodes (Moore).—A very lovely Fern from Ecuador and Peru, doing well in the greenhouse, so it is probable that under natural conditions it occurs at high altitudes. The fronds are borne on slender dark brown glossy stipes from 9 to 18 inches long, drooping, three times divided, the ultimate divisions obliquely cuneate, the lower edge straight, the upper one rounded, usually finely lobed or toothed; when young of a delicate pink colour, gradually changing to pale green. The habit of the plant makes it an excellent basket Fern; also most suitable for the rockery, which is, indeed, the proper home for all such Ferns.

A. cuneatum (Lang et Fisch.).—This is the Maidenhair Fern so well known and extensively used where Ferns are appreciated. In all stages of growth it is most useful—in thimble pots or as large permanent specimens, such as are frequently seen at exhibitions.

A. decorum (Moore).—A great favourite, producing large fronds from 9 to 18 inches long, and from 5 to 10 inches across the base, three or four times divided, the ultimate divisions rhomboid or cuneate, with the outer edge distinctly lobed, of a light rich green colour, with a firm texture. The fronds are spreading, slightly arching, on stiff, dark, polished stipes. In any stage it is very handsome, and the fronds are most useful for large floral work, the segments being larger than those of *A. cuneatum*. It is a native of the Andes of Peru.

A. gracillimum (Moore).—This lovely Fern is now well known and very highly esteemed for bouquet work and for furnishing purposes. It is of garden origin, and is a finely divided form of *A. cuneatum*, the fronds being decomposed, with small imbricated segments, similar in form to those of the tyre, of a deep green colour, and extremely graceful in all floral arrangements. No collection should be without it, as it is very easily managed, coming freely from spores and generally true to character.

A. formosum (R. Brown).—A very handsome vigorous-growing species from the cooler portions of Australia and New Zealand, producing strong copiously divided fronds from 1 to 3 feet high, broadly deltoid in form, three or four times divided, the final divisions dimidiate, the lower edge straight, while the upper one is rounded and rather deeply lobed, of a deep green colour. As a permanent decorative Fern for the greenhouse it can scarcely be surpassed, because it is evergreen and grows so freely, while its large ample fronds are extremely valuable for furnishing, especially for the dinner table.

A. Luddeimannianum (Hort.).—This is a charming little Fern, far too rarely met with, on account, perhaps, of the difficulty attending its cultivation—at least, as far as increasing it rapidly is concerned. The fronds are from 6 to 12 inches high. I have never seen them more. The slender stipes are branched about half or a third of the way up, and are of a reddish-brown colour. The pinnules and segments are more or less confluent and clustered at the extremities of the ramifications, forming broad, crested, tasselled heads, the weight of which gives the fronds a slight but graceful curvature. Without doubt this is one of the most distinct of all the *Adiantums*, and it likes thorough drainage, light fibrous soil, with a very humid atmosphere without a high temperature. I have found it thrive freely under

a bellglass or in a small case, and with the surface clothed with *Selaginella*.

A. palmatum (Moore).—A handsome species from the Andes of Peru, producing large graceful fronds from 1 to 2 feet long, triangular in form, tripinnate, the final segments nearly an inch across, semicircular or fan-shaped, the outer edge deeply lobed, of a fresh green colour, with a firm texture. Of comparatively recent introduction, it is not yet so frequently seen in our collections as it will be, because it is so striking a plant that it must become a general favourite.

A. Pacottei (Hort.).—A very charming little Fern of garden origin, producing dense tufts of tri or quadri-pinnate fronds from 4 to 8 inches long, with the segments thickly imbricated, of a deep green colour. This is a very distinct form, and much esteemed, but as yet little known. It is destined to become a general favourite, as the small stout-textured fronds will be extremely useful for buttonholes. Happily, it is most easily raised from spores, and the plants thus raised are well characteristic of what may be regarded as the typical form.

A. rubellum (Moore).—A very charming little species, producing fronds from 6 to 9 inches high, deltoid in form and bipinnate, not very copiously divided; the segments cuneate, with the outer margin deeply lobed and toothed; when young of a deep reddish pink colour, gradually changing to light green, and in the former state it is extremely handsome. This is a little gem for chinks of the rockery or for growing in pans in a case. Native of the Andes of Bolivia.

A. reniforme (Linn.).—In this we have a plant which is very similar to *Trichomanes reniforme*, producing erect, simple, reniform fronds from 1½ to 3 inches across, with a tough texture, borne on slender stipes. It should be in all collections and treated most lovingly. Under a handglass or in a case it does well, because it enjoys a damp atmosphere. When the latter is dry it is very liable to be infested with thrips, and these creatures quickly disfigure the fronds. It is found in Madeira and Teneriffe, while a variety of it crops up in Bourbon and Mauritius.

A. Williamsii (Moore).—This is frequently called the Golden Maidenhair Fern on account of the young fronds being sparingly covered with a golden powder. It produces fronds from 1 to 2 feet long, more or less deltoid, tri or quadri-pinnate; the ultimate segments semicircular or rhomboid, with entire edges of a pale green colour. It comes from Peru, and is a very vigorous grower, and very useful as a decorative Fern, while the fronds are desirable for cutting.—T.

THE FORMATION AND KEEPING OF WALKS AND DRIVES.

(Continued from page 259.)

Now as to keeping. If left for months without any attention the horses make a track along the centre, and between that and the wheel marks on each side a ridge is left which keeps the water from running to its proper channel at the sides, and so it soaks into the crust of the road to its material damage. The moveable gravel on the top must be constantly raked on to the parts where it is wearing, and when it gets too thin to cover them more must be added. A road well kept in this respect wears more equal, for the simple reason that there is no track to follow, and therefore the traffic will be confined to the centre.

When a road gets worn into holes and thoroughly out of repair, perhaps the best thing to do with it would be to pick the whole up, rescue what stones there is in it, and add what more is required to make it substantial. This is best done by clearing a 6 or 8 foot width, level the bottom, and then place the stones out of the next width on it, add sufficient fresh stone to bring it up to the required depth, and if there is any gravel worth saving toss it back on the top, level the bottom and proceed with the next width; thus in a manner it may be called trenching. To mend an odd hole the stones should be taken out or loosened some little distance round, and the whole well rammed in to the proper level. When it is desired to strengthen an existing road run the pick diagonally across the roadway 6 or 8 inches, thus breaking the crust, when a coating of well-broken stone may be added and covered with fresh gravel.

It is also important that the drains be seen to frequently. The gratings must be as far as possible kept clear of leaves, &c., and the cavities below them cleared of any grit that may accumulate in them before they get filled and begin running into the drain.

Garden Walks.—These may be made of anything that is hard enough to keep a firm dry surface—brickbats, freestone, clinkers, &c., may be used, as there should always be sufficient

good gravel on these to hide whatever is in the bottom. The same principle of forming a good sound foundation must be followed in making these. In pleasure grounds drainage should always be carefully provided, but in a kitchen garden with Box edging there is not so much need for drains, as the wet soaks into the soil. In making a walk close to, or near a mansion, the side of the walk next the wall should be kept up the same as if it was the centre of the walk, as shown at fig. 65, so that the water may not lodge there and cause dampness in the building. It is always necessary to have a drain to carry off the rain from the roof, and where there is a border between the walk and the mansion, as shown in our section, the drain for this purpose should be confined as far as possible within the border, so that it can be seen to in case of stoppage without breaking into the walk. These should always be laid with glazed socket pipes

Fig. 65.

with their joints properly cemented, and to provide for any defective joints it is a safe plan to have them below the level of the foundations.

Young men sometimes find a little difficulty with regard to the level at the junction of two walks running in opposite

Fig. 66.

directions on sloping ground. Take the instance of such a case in a kitchen garden. Suppose the line *a*, fig. 66, represents the slope of the ground, or say the level of the edge of the walk

Fig. 67.

A in our ground plan, fig. 67. Drive a level peg exactly in the centre of your cross walk B, fig. 67, in a line with the edge A and level with it. Level from this peg for the edges, placing other pegs c c at each side. The same operation has to be gone through at the other end of the cross walk, when the levelling of its sides may be proceeded with. As will be seen by the two lines in the section, fig. 66, *a* representing the height of edges; A, fig. 67, and the dotted line B, the level of the cross walk. The latter is below the level of the former on the high side, and above it on the lower side at their junctions, having the edges of both walks levelled up to within a foot of the pegs c c. From these measure along each edge a distance equal to half the width of the walk, as at D D, and insert pegs exactly where the Box edging is to come. From these points stretch a line across the corner, as shown by the line E, and level the ground from the one point to the other, continuing it out to the peg c. This will gradually verge the one level into the other. Now place the looped end of a piece of string over the pegs at D D from c, draw lines crossing at E, and from this centre carefully mark the quarter of a circle from D to D to form the corners, by drawing the sharp point of a peg along the level surface. Right-angle corners should always be so rounded off, for as a rule square corners get trodden down and become unsightly.—R. INGLIS.

MIGRATORY BIRDS.—I may mention the circumstance that the nightingale was heard many times in the district of Gravesend during the latter half of March. We can scarcely suppose that in the case of a migratory species some precede the rest, either coming alone or joining some other party of birds, and they have evidently not arrived yet as a body. I infer, therefore, the suggestion is right which I have somewhere read, that a few of these birds winter with us and are heard early in

spring, or even at the commencement of the year occasionally.—J. R. S. C.

CELERY.

WHEN anyone can have this excellent vegetable fit for use from the end of July till the following April its culture surely deserves more attention than it generally receives, more especially its treatment in the trenches after being planted out. By treating it according to the nature of the soil much can be done to prolong its season for use. The soil here is very heavy, and for a supply in the spring months we sow the seed in April, grow it in the usual way till ready for planting out. We make trenches not very deep and 3 feet wide, which allows sufficient space for planting three rows in the trench. After being a month or six weeks planted, or according to the progress that the plants have made, they receive a slight earthing up about 2 inches deep with the natural soil.

They receive no other attention except watering in dry weather, and tying the plants with matting to prevent the wind breaking their outer leaves, until the month of October, when we save all the new-fallen Beech leaves, and when dry we pack them in the trench to blanch the Celery instead of using the soil; but before doing so we make a wall of soil about the height of the plants on each side of the trench to keep the leaves in their place, and to prevent them being blown about we cover with sawdust. By adopting the above plan at present we have fine fresh Celery quite different from that obtained by the old practice—namely, surrounding the plants with heavy wet soil. The advantage gained by using the leaves when lifting the Celery in frosty weather will be easily seen.—DAVID MURRAY, *Culzean Gardens, Maybole.*

THE CULTIVATION OF VIOLETS IN FRAMES.

Now that the time is at hand for commencing operations to ensure the successful cultivation of this the sweetest of winter and spring-flowering plants, the subject is worth consideration, as the pits and frames are now being cleared for other purposes, and frame cultivation of Violets is at an end for this season. But we must begin our task again if we wish to have a healthy stock of plants and abundance of large sweet-scented flowers during next winter.

The system we pursue is planting single crowns so as to cover the entire surface of the bed, and we are so satisfied with the results as to totally discard the clump system, except for pots. Our mode of procedure is to plant small side shoots or sets 6 inches apart in a nursery bed, and when they have made good strong crowns they are planted out about the middle of May in a rich prepared border 15 inches apart. During the summer they require looking over once a fortnight to remove suckers and surplus runners, leaving four or five of the strongest to each centre crown, and when they have formed a knot to stop it. The result will be the nourishment will form a good plump crown, instead of expending itself in useless suckers and runners. Small pegs should be used to fasten them down, to prevent the wind blowing them about until they have taken root.

Towards the end of September the pits or frames should be prepared. They should have a south aspect, and if there are pits that can be spared adjoining a house heated with hot water so much the better, as small perforated air bricks can be let into the dividing wall, and in frosty weather the advantage will be great, as ventilation can be afforded without admitting the cold air. The bottom of the pit can be covered with a layer of brushwood and leaves made firm, on the top of which place about 12-inch depth of good loam to within 6 inches of the glass. The plants can then be carefully lifted and placed out, pegging the radiating crowns so as to cover the entire surface of the bed, as there is no fear of the foliage overcrowding, each crown having only its proper supply of leaves, all useless wires being removed as soon as they appear. Where there are no pits to spare such as I have described, we must have recourse to the common wooden frame, which, when elevated on a layer of faggots, filled with loam, and planted like the others, a lining of fermenting material can be applied to the base, and the heat will rise into the frame, which of course must be well ventilated. I prefer a loam of a rather strong tendency to one of a sandy character, as in the former the plants produce flowers of a deeper colour; whereas the absence of moisture in a sandy situation causes the plants to become infested with red spider, which soon destroys the foliage and greatly weakens the constitution of the plants. If possible sets for planting should be procured from plants that have been liberally treated the previous year, for, like the Strawberry, they are apt to degenerate rapidly if left to themselves.

For general purposes no better sorts can be grown than the varieties known as the Improved Neapolitan as a double flower, and

Lee's Odoratissima for a single, both of which are in all respects a decided advance on the old Neapolitan and the Czar; although there are some good sorts, such as Marie Louise and Belle de Chatenay, that can be grown as a speciality, and amply repay for so doing. I consider the two first-named are as yet the best all-round varieties that can be had for frame cultivation.

The foregoing remarks may be of use to those who have to produce a large supply of this favourite flower during the depth of winter, and to those who have not tried single crowns I would advise a fair trial during the coming season; and if properly carried out they will not revert again to the clump and row mode of planting, as they will find that in the same space finer flowers and larger quantity can be grown on the "single crown system."—VIOLETA.

NOTES ON ORCHIDS.

DISA GRANDIFLORA.—When these plants are grown amongst other cool house Orchids they should have the coolest and most airy position in the house. They will not grow strongly in a close atmosphere. Abundance of water should be given them during the summer both at the root and over the foliage—in fact, in well-drained pans it would be difficult to give them too much. The moss on the surface should be kept growing and healthy both summer and winter, and the water required to insure this will be found to suit Disas exactly. From the present time these plants would do well in a cold frame, provided they can have plenty of light and yet be shaded from strong sun, but in this position they are more apt to be neglected. The other day I saw a very good method of treatment at Woolton Wood, which is worth the attention of those interested in these plants. They were growing at one end of the Odontoglossum house, and the lower squares of glass at the end close to the Disas had been removed and the spaces filled with perforated zinc, the holes being small. By this means abundance of air is admitted to the plants, which they evidently enjoyed, for they were sturdy and healthy.

SOPHRONITIS GRANDIFLORA.—A charming little Orchid when well grown; its large bright flowers give it a cheerful appearance, totally distinct from all others that are flowering at this season of the year. It will grow very well on small blocks of wood, but in this position requires more attention in watering than when grown in small shallow pans. It should be suspended from the roof, and if employed freely or alternately with Odontoglossum Cervantesii or even the beautiful and distinct O. Rossi majus, which also flowers about the same time, the effect is all that can be desired. The Sophronitis is an obliging Orchid, for it appears to thrive well either in a warm or a cool house, and I have seen some grand specimens in a stove with brighter flowers than when in a cool house. It delights in a little heat, such as afforded in an intermediate house, while making its growth, but when at rest should have cool house treatment, which insures a vigorous growth the following season. Although its flowers are brighter in heat they do not last quite so long as in a cooler house. To grow this Orchid successfully too much rooting material should not be given it; but the pans should be liberally drained with crocks and charcoal, a little peat fibre and living sphagnum being used for the compost.

CÆLOGYNE CRISTATA.—Where choice flowers are wanted for cutting this Orchid should be largely grown, for it is free-flowering under good treatment. It is also one of those Orchids that will bear pushing forward in heat or retarding to suit the convenience of individual cultivators. To flower it in succession with the least trouble a little heat should be applied to a number of plants, which will push them forward more rapidly into growth, while the remainder can be brought on naturally in the cool house. It is much better to assist them now than to have to unduly push them forward during the worst months of the year. When grown specially for cut flowers the plants can occupy pans, or will be found to do well in baskets suspended from the roof. Plants in 5-inch and 6-inch pots are valuable as single specimens for vases in rooms, where they will stand for a time without injury provided gas is not employed.

Potting should be attended to if it is required as soon as the plants have flowered, or as their new growths are issuing from the base of the pseudo-bulbs. In potting they should be well elevated above the rim of their pots or pans, which should be abundantly drained. They will thrive in a compost of peat fibre, three parts to one of sphagnum moss, with lumps of charcoal freely intermixed, and to which the roots will cling tenaciously. If potting is not needed remove the surface moss and all decomposed material possible and supply fresh, working the moss well in amongst the pseudo-bulbs. If the plants are large and crowded remove portions carefully, with as many roots as possible. It is a great mistake to allow the pseudo-bulbs of these plants to become crowded, for the flowers, instead of being large and plentifully produced, will be small and few. With a little care plants can be kept furnished with large

pseudo-bulbs, which are very much better than double the quantity of smaller ones. The portions removed, even if not having a lead upon them, will generally break back, and if placed in 5-inch and 6-inch pots become thoroughly established in a short time, making in the second season grand flowering plants. Pieces taken off with a lead and a few roots will in a season make strong plants that will flower well the following spring. Abundance of water should be given when the plants are growing actively.—W. B.

CYPRIPEDIUM CAUDATUM.—One of the finest flowers of this remarkable species that has come under our notice was grown by Mr. H. M. Pollett. The dorsal sepal is 6 inches long, and the striking caudal appendages or tails $25\frac{1}{2}$ inches in length. The bloom before us is highly effective, and a conclusive example of superior cultivation. Mr. Pollett has also sent us very fine flowers of the charming *Dendrobium Devonianum*, the labellum being good in colour, markedly fringed, and $1\frac{1}{2}$ inch in diameter.

PSORALEA PINNATA.

PSORALEA is a rather large genus of Leguminous plants, mostly from the Cape of Good Hope, and related to *Indigofera* and *Clitoria*.

Fig. 68.—*Psoralea pinnata*.

Some are very attractive little shrubs for greenhouse cultivation, but are by no means generally known in gardens. *P. pinnata*, of which a flowering shoot is represented in fig. 68, is one of the best of the sixty or seventy species that have been described, and is also one of the oldest known in this country, having been cultivated in the seventeenth century. It is a compact shrub, attaining a maximum height of 4 or 5 feet, but is seldom seen so large as that. The leaves are neatly pinnated, with three or four linear pinnæ. The flowers are produced freely but singly on short pedicels from the axils of the leaves near the upper parts of the growths, their colour being a bright blue, shaded lighter or nearly white in the centre.

A compost of peat and loam, with the ordinary treatment of Cape

plants grown in a greenhouse, suits the plant, and it can be propagated by cuttings.

CHRYSANTHEMUMS IN TUBS.

WHERE there is a large conservatory to be kept gay the *Chrysanthemum* deserves the foremost position among winter-flowering plants. There are many ways of growing it to perfection, and all commendable in their way. In well-prepared soil in the open garden they will yield abundance of flowers, but for conservatory decoration a few made-up specimens in tubs are very effective.

The great advantage possessed by tubs is that they afford a greater root-space than pots, and as the *Chrysanthemum* is a very gross feeder the value of this can scarcely be over-estimated. Then pots are very liable to be broken, especially in places where the conservatory is a distance from the houses, and the plants have to be carried thither. I have on many occasions seen pots rendered useless either from a kick or a sudden jerk against the ground.

Those who have no tubs and are not inclined to have new ones made may use old oilcasks by sawing them through the middle, putting two or more iron handles to them, then bore a few holes in the bottom for the escape of water. If a coat of paint be given the tubs are complete and will answer as well as anything, and with due care will last a long time. Of course if new ones are preferred they can be made of any size or shape that may be considered the most suitable. Bricks are as good as anything I have used for drainage with a few crocks over them, and to keep the drainage well open I prefer a layer of moss.

Now as to soil. I employ a compost of loam one part, burnt refuse one part, the remainder consisting of thoroughly decayed farmyard manure, brick rubbish, and road sand well mixed together some time before it is wanted for use. The number of plants to be grown in each must depend upon their state about the third week in June, when they should be well established, but not root-bound, in 24-size pots. I have placed three, four, and five in a tub, and the best of *Elaines* I ever saw were five plants grown together in one tub. By this means the tub can be better filled at the commencement, as it allows of a good plant being placed in the centre. It is a good plan to leave plenty of room for one or two top-dressings during the time the plants are growing, and one after they have been disbudded. For this purpose I have used a thin covering of fowls' dung, over which a layer of fresh loam is placed. This not only avoids the unpleasant use of liquid manure in the conservatory, but is a great help to both flower and foliage when washed down to the roots with clear water.

Any variety will do well in tubs, but a little forethought accompanied by good taste may help to bring about good results—that is to say, if the plants of *Elaine* are carried up the centre, with two of the pretty *La Frisure* neatly staked around the outside, and a few pots of *Isolepis gracilis* arranged hang over the tubs.—G. M. W.

HISTORICAL JOTTINGS ON VEGETABLES.

THE CELERY AND THE PARSNIP.

BOTH the Celery and the Parsnip find their natural place in the extensive order of umbelliferous plants, wild examples of which meet us in every field and beside every hedgerow, and which offers much perplexity to the student of plants, owing to the great similarity amongst some of the species. It has not a few plants of virulently poisonous character, and a larger number that are useful either for food or medicine, while there are others with no qualities of any importance. The order also offers numerous illustrations of the statement, that by cultivation unwholesome plants may not merely be modified, but almost transformed in their qualities and manner of growth. All parts of Europe have yielded examples of the Celery (*Apium graveolens*) growing wild, and showing a marked preference for marshes near the sea or the edges of streams approaching their termination. The Latin specific name (and it is to be regretted that this, as in other instances, has been given to more than one species) points to the powerful odour attached to the plant, which at an early period received the popular name of Smallage. It was also sometimes called Wild Parsley, although having scarcely any of the qualities of that plant, and even the cultivated form was by some old gardeners styled Macedonian Parsley.

Evidently as a wild plant Celery was known to the ancients, but the Romans, clever though they were as gardeners, had not discovered how to blanch the stalks, nor does it appear they cultivated it. The physicians used the root to form a decoction, and Pliny recommends the plant, stating that it counteracted the effects of bites or stings.

Probably our familiar name for it came from the Greek appellation, which alludes to the curling of the young leaves; for a century or more it was commonly written "sallary." With the old English herbalists, as Smalage, the species had also a medicinal repute. They prepared an ointment from the leaves, and squeezed the juice from the stem, which was mixed with honey, to cure sore throat; and, now-a-days some writers upon dietetics commend the stalks of Celery as excellent in their influence on the health.

Frequently do we lose all clue to the history of those who have made valuable discoveries, and thus it happens that the original grower of Celery for the table as we now see it is quite unknown, and also the exact date of its first cultivation. There is only obtainable this item of information from the excellent John Ray, that it was one of the plants brought to table as somewhat of a novelty early in the seventeenth century; and he notes the fact, that without careful attention, Celery very soon reverts to its natural or wild condition. Occasional remarks in other authors imply that, though the blanched stalks were then produced, the young foliage was also eaten, probably chopped up and mixed into a stew. Evelyn adds another item, that Celery came to us from Italy, where it had been known as Celery for only a few years previous to its introduction. He recommends that it be accompanied by vinegar, oil, salt, and pepper; we now prefer to take it with one of these condiments as a relish to cheese when we eat it raw. And he declares that for "its high and grateful taste at our great men's tables it is ever placed in the middle as the grace of the whole board."

So that, although the plant is one of our natives, no Briton can claim the credit of having tamed the wild species, but we may perhaps boast of some skill in producing good varieties, also in growing very fine examples. Loudon refers to a large plant dug up near Manchester, weighing 9 lbs. when washed, and over 4 feet in height; when cut it was crisp and of good flavour. The Turnip-rooted Celery was, it is said, brought from Germany to England about a century ago; it is mentioned by Mawe and Abercrombie, and, though hardier than other kinds, this has never been a favourite here, yet it has retained its German repute. Another variety, which seems now to have been lost sight of, was a tall sort grown in Samos, from whence the seed was sent to Norfolk in 1797. Only four or five kinds are noticed in books of gardening of the reign of George III., but the consumption of Celery in and near London was considerable, so that large quantities were raised by the market gardeners round the metropolis. Abercrombie, indeed, speaks of it as an article which many families required daily during several months of the year.

The Parsnip (*Pastinaca sativa*) may have taken its Latin name from the circumstance that the root in its shape resembled a kind of digger named "pastinum," as some assert, but this explanation is not highly satisfactory. Nor is it certain that "Parship" is only a perversion of the Latin word, yet it may be so, unless the "nip" or "nep" bears an allusion to another group, perhaps once supposed to be akin to the Parsnip. This plant, possibly less common than in the olden time, still grows wild upon chalky downs, in Wiltshire for instance, conspicuous during July and August by its yellow flowers and glossy leaves. Although less objectionable in its qualities than is the wild Celery, it is of no value while it is an uncultivated plant; but hogs, when at large, are attracted to the roots, which they dig up and devour. But there were formerly some of the believers in that medical lore which was oddly combined with astrology, who set great store by the seeds of the wild Parsnip, containing as they do a pungent essential oil; these were administered to those suffering from various forms of intermittent fever, or a decoction prepared from them. Afterwards, when the Parsnip became the garden plant, the seeds of that kind were commonly sold by druggists in place of those of the wild plant, much to the vexation of the herb doctors, for Culpepper and others maintained that the seeds of the "tame" Parsnip had little virtue in them.

Early in the Christian era we find the cultivation of Parsnips referred to, and it is stated that the roots were sent from a district of Germany upon the banks of the Rhine to the capital of the Roman Empire, to supply the table of the sensual Tiberius, who, as we know, was apt to pamper his appetite with articles much less wholesome. In serving up this vegetable the Romans removed the pith, which they did not eat, and poured over it a sauce compounded of honey, so adding "sweets to the sweet." Their method of culture had its peculiarities; one of these was that they took up the plants and replanted them when the roots had attained some size. They also regarded it as a good plan to allow them to be in the earth through a second season before eating them. It would seem the leaves were occasionally cooked, and a belief that the plant warded off the bites of serpents led some persons to carry about habitually some part of the Parsnip.

Though the Romans introduced various fruits and vegetables to these shores, we cannot credit them with the fact of having brought

us the Parsnip, and it is all but certain that the Flemings, who fled to England from the persecutions carried on by that tyrant Philip II., and who are known to be the first cultivators of the Carrot here, did also raise the first English Parsnips. This would be about the middle of the sixteenth century, and the place probably the soil of Kent or Essex. Gerarde, a man quite up to the level of the naturalists of Elizabeth's time, was yet somewhat puzzled by the Parsnip, which he seems to have half suspected to be a variety of the Carrot, but afterwards acknowledges their distinctness. His friend Plat had manufactured bread from Parsnip roots, and he himself believed they were superior to those of the Carrot and Turnip. Turner alludes to the custom of eating Parsnips during the Lenten season. Ray utters a word of warning that old Parsnips might possibly give rise to delirium. Rather slowly the Parsnip came into general use, but for many years only a single cultivated form was to be seen in English gardens. Several varieties, however, had been grown in Normandy and the Channel Islands; one of these has roots of enormous length, and is still made to yield heavy crops for the feeding of cattle. The Parsnip has been highly commended as a fatterer, answering indeed better than its relative the Carrot, yet it is very moderately used for that purpose in Britain; and with many of the Scotch it is a more favourite vegetable than it is to the south of the Tweed.—J. R. S. C.

ROSES NIPHETOS AND SAFRANO.

It would indeed be a poor Rose that had no admirers or advocates, and I felt sure when I penned my remarks (page 104) that someone would be sure to defend the case of that popular variety Niphetos. I wrote of the qualities as winter flowerers, and have no desire to withdraw one word that I have written respecting the merits of these two varieties. I have had abundant opportunities of testing them side by side both in pots and planted out under various circumstances and conditions. It must be understood that by free winter-flowering varieties I mean those that are best adapted to grow and unfold their delicate buds, say from the month of November until the early part or middle of February, which comprise the worst months of the year in this locality where fogs predominate. Rose-forcing is thus conducted under difficulties, and I hope that my friend Mr. Iggulden enjoys a pure bright atmosphere free from the evils which surround us in this neighbourhood.

Niphetos lacks vigour as compared with Safrano, and during the months named will not make growths half so strong or so numerous as those of Safrano; in fact, it will not grow so rapidly or with the same freedom either planted out or grown in pots, under exactly the same conditions. If a variety does not possess vigour of habit it will not produce half so many buds as a stronger variety will do. Growth must be constant in order to yield a continuous supply of buds, and this is the character of Safrano. Mr. Iggulden says, "One good bloom of Niphetos is worth four Safrano buds," but during the winter the former will not produce "good blooms;" they are only buds, and smaller than those of the latter, which will produce fully twice as many, one being fragrant and the other not. To write accurately there is no variety that is really scentless, for all have a slight perfume; but what is the scent of Niphetos, Etiole de Lyon, Capitaine Christy, Magna Charta, Baronne de Rothschild, Countess of Oxford, and many others, compared with that possessed by Safrano, Gloire de Dijon, the Hon. George Bancroft, La France, Bessie Johnson, Marie Baumann, and many others, even when grown under the same treatment?

I freely endorse the editorial remarks (page 195) that there are more blooms of "Niphetos sold in London at the present time than those of any other Rose," and why? Simply because a preference is given to white flowers by the florists, and the price realised for the former would be considerably more than for coloured flowers, however choice, early, or delicate. It is exactly the same with the Rose as the Camellia, for there is no difficulty in disposing of white flowers, often at a very high price, while there is much difficulty in selling red or other colours at less than a third the price of the others.—WM. BARDNEY.

CRYSTAL PALACE SPRING SHOW.

APRIL 4TH AND 5TH.

THE first of the series of horticultural exhibitions announced for the present year by the Crystal Palace Company was held on Friday and Saturday last, and gave hopeful evidence of what may be expected at the later and larger shows. An exhibition so early in the season is quite a novelty, and it was regarded by the projectors almost as an experiment, the success achieved consequently forming an agreeable surprise, and furnished additional encouragement for further efforts. In the arrangement of the exhibits a new departure was also made, for the centre transept from the great organ to the stage was solely devoted to the show, four rows of tables being arranged in parallel lines. The four corners were devoted to the groups, a magnificent semicircular group from the Palace collection occupying the most prominent position at the base of the orchestra. The great advantage of this method was that, though a less extensive effect was produced than under the ordinary system, there was a greater concentration, and visitors were enabled to inspect the exhibits without having to wander half over the Palace. The tables employed, however, would have been greatly improved had they been draped with baize or some material to conceal the tressles, but with this exception the general organisation was all that could be desired, and was highly creditable to the garden Superintendent,

Mr. Head. The later shows will be held outside the Palace in marquees, in consequence of all the available space inside being occupied with contributions to the International Exhibition.

Bulbs.—Several classes were devoted to these, the principal being that for thirty-six Hyacinths, in which two good collections were staged. Messrs. H. Williams & Son, Fortis Green, Finchley, won chief honours with strong plants bearing massive well-developed spikes, the leading varieties being L'Obelisque, King of the Blues, Czar Peter, Gigantea, Grandeur à Merveille, La Grandesse, Garrick, Mont Blanc, and Von Schiller. Mr. J. Watson, Newcastle-on-Tyne, took the second place with smaller but fresh plants. Messrs. Williams & Son were the only exhibitors of thirty-six Tulips, their collection, for which the first prize was adjudged, comprising some fairly good plants, but rather too much advanced. Keizer's Kroon, Joost Van Vondel, Vermillon Brilliant, and Canary Bird were notable varieties. The same exhibitors had the only entries of twenty-four Tazetta Narcissus, and secured a similar award for well-flowered specimens, the varieties being Charles Dickens, yellow petals and orange cup; Sir Walter Scott, white petals, gold cup; Bathurst, yellow petals, orange cup; Grand Monarque, white petals, lemon cup; and Gloriosus, white petals, orange cup.

Cyclamens.—The competing and non-competing collections of Cyclamens formed a strong feature in the Exhibition, the flowers in the majority being remarkably abundant, large, pure white, and richly coloured. For thirty-six plants Mr. H. B. Smith, Ealing, gained the leading position with beautiful examples, some of the plants bearing over sixty flowers, with broad substantial petals. Mr. Hill, gardener to H. Little, Esq., Hillingdon Place, Uxbridge, was second with healthy plants, the flowers being mostly distinguished by their rich shades of crimson. Mr. J. James, Farnham Royal, Slough, took the third place with dwarf free plants. Three other collections were entered in this class, all in some degree meritorious.

Cinerarias.—Four competitors entered the class for twelve Cinerarias, Mr. J. James being an easy first with dwarf compact plants, bearing massive richly coloured flowers of the usual quality distinguishing the Farnham Royal strain. Messrs. J. Carter & Co. were second with smaller plants, bearing neat and diversely coloured flowers. Mr. Hill was third, his plants being rather backward. There was some dispute as to the accuracy of these awards, the second prizetakers protesting that in several cases in the first-prize collection two or three plants were grown together in one pot, and that in this way more than twelve plants were shown. The objection was, however, overruled on the terms of the schedule. In the amateurs' classes Cinerarias were small. Mr. Todman, gardener to H. Hearn, Esq., Upper Tooting, having the best, followed by Mr. Hill and Mr. Wiggins. Three good collections of Lilies of the Valley were entered, each comprising twelve 8-inch pots. Mr. J. Watson was first with very abundant handsome spikes, fifty to sixty in a pot, but the foliage was scarcely enough developed. Messrs. H. Williams & Son were second, also with good flowers; but in this case the foliage was rather too much advanced. Messrs. J. Carter & Co., High Holborn, were third, their flowers being not sufficiently advanced.

Azaleas.—Mr. C. Turner, Slough, was the premier exhibitor of the Azaleas, which were mostly in 8-inch pots and trained in the form of small cones about 2 feet high. They were exceedingly healthy, flowering profusely, and represented a number of superb varieties. Very noteworthy were Comtesse de Flandres, with large rosy crimson flowers; Pucelle de Gand, pure white, large, fine rounded petals; Duc de Nassau, rich crimson, very free and handsome; Duchesse de Nassau, rosy-scarlet; Mdle. Marie Van Houtte, A. Borsig, and Flag of Truce, three excellent double white varieties, together with Roi d'Hollande, very fine; Ceres, Mrs. Turner, and Stella. Mr. H. James, Lower Norwood, was a good second, his plants being of similar size, but globular in form and profusely flowered. The varieties Bernhard Andreas and Alba Apollon, Bijou de Paris, and Roi d'Holland were the best.

Pelargoniums.—Messrs. H. Williams & Son secured the chief position with twenty-four show and decorative Pelargoniums, healthy well-flowered plant of moderate size; Scarlet Gem, Defiance, scarlet; Virginalis, white and crimson; Le Géant, Madame Favart, and Albino, white with crimson feathering, being the best varieties. Mr. C. Turner was second with a less even collection, but Rosetta, purple crimson, very free; Joe, flowers large; Lady Blanche, white with crimson feathering; Mad. C. Koling, white, veined with pink, were notable.

Auriculas were exhibited by Mr. C. Turner, who was awarded the first prize in the two classes for twenty-four show and the same number of Alpine varieties. In both collections the plants staged were very healthy and freely flowered. Amongst the show varieties Beauty, Charles Perry, Glory, Lord of Lorne, Blackbird, Campbell's Green Edge, and Campbell's Confidence were the best, while amongst the Alpines were Troubadour, Tennyson, Unique, Gorton's Diadem, and Corsair; certificates being awarded for several others that are described below.

Only one collection of twenty-four Chinese Primulas was staged, Messrs. Carter & Co. being adjudged the premier award for well-grown plants of their numerous varieties. The colours were rich and varied, the Holborn Blue, Red, Carmine, Vermillion, Magenta, and Pink being in good condition, as were also Rosy Morn, Rosy Gem, and Snowflake. In the amateurs' class Mr. Todman was the only exhibitor, being awarded the first prize for rather small plants.

Amaryllises were shown by Mr. Hill and Mr. W. White, gardener to C. Dorman, Esq., The Firs, Laurie Park, but the flowers were very small in both cases, though the colours were bright. Mr. Wiggins had the only dozen pots of Mignonette, gaining the first prize with large dense heads of flowers tight to twelve in a pot.

Groups.—Three effective collections were entered in the class for a group of stove and greenhouse plants arranged in a space of 100 square feet, and being placed at the corners of the centre transept they contributed much to the beauty of the Exhibition. Messrs. J. Laing & Co., Forest Hill, were awarded first honours for a very bright arrangement of bulbous plants, Azaleas, Heaths, Amaryllises, Orchids, Caladiums, Ferns, and Palms, the richness and variety of colour in this group undoubtedly giving it the preference. Mr. H. James was accorded the second prize for a group that in regard to lightness, elegance, and absence of formality was considered by many superior to the first; but although there was a good number of healthy well-flowered Orchids with bright colours and elegant Palms, the group as a whole presented a less showy appearance. Mr. C. Turner was third with a light and

graceful but slightly thin group of small Azaleas, Gloxinias, Abutilons, Palms, and Dracenas, edged with Isoplepis.

Miscellaneous.—By far the most extensive and brilliant collection of plants was that from the Crystal Palace houses. This occupied the whole space in front of the orchestra, and comprised some hundreds of admirably grown bulbous plants, such as Hyacinths, Tulips, Lachenalias, and Narcissus, with Azaleas, Lilies of the Valley, Cytisus, Polygonatums. Without doubt this was one of the most handsome groups ever produced in the Palace grounds. On the opposite side, at the base of the stage, Messrs. Barr & Son, Covent Garden, had one of the largest collections of Daffodils they have yet shown, and it was certainly the most tastefully arranged. There were eight boxes each 9 feet long, filled with moss, in which the bottles containing the flowers were plunged to the necks, a few Isoplepis and other foliage plants being employed to break the uniformity of colour. Hundreds of varieties were represented in all the sections, a few clumps of Anemone fulgens being added to diversify the effect. Mr. T. S. Ware, Tottenham, contributed a choicest selection of the best varieties of Daffodils, together with flowers of several other hardy plants, such as Chionodoxas, Muscaris, Anemones, and Primulas. Messrs. Carter & Co. had a fine group of Cinerarias with neat flowers of many rich colours, showing the merits of the strain; Hyacinths, Tulips, Deutzias, and Spiræas were also employed liberally with good effect, and a collection of choice hardy plants were staged. Messrs. A. Waterer, Woking, showed an interesting collection of hardy Azaleas, mostly double, and representing some fine shades of yellow and pink. Primroses and Andromedas were similarly good. Mr. J. H. Brack, Sevenoaks, sent two boxes of Rose blooms; Messrs. Hooper & Co., Covent Garden, showed a plant of a new tree Carnation named C. H. Hooper, pale yellow ground, edged with crimson, very free; and Mr. J. Mayo, Oxford, showed two boxes of Rose blooms. Mr. H. B. Smith, Ealing, contributed an extensive collection of vigorous profusely flowered Cyclamens. Mr. R. Clarke of Twickenham also having a large group of Cyclamens in similar condition, Mr. Wiggins staging a group of Cinerarias and Cyclamens. To all of these extra prizes were awarded.

Certificates were awarded for the following plants:—

Auricula Douglas's Conservative (Turner).—A white edge show, small pip, paste very broad, black body colour, truss of eleven flowers.

Cyclamen Rose Gem (Hill).—Previously described.

Cineraria Marmion (James).—A rich velvety-crimson self, the flowers broad and massive.

Cineraria Lord Beresford.—A purple-crimson self, lighter in the centre. Very bold and effective.

Auricula Mungo McGeorge (Turner).—A shaded Alpine, pale gold centre, crimson body colour. Large pip and neatly formed.

Auricula Douglas's Mrs. Moore (Turner).—A green-edged variety, pip of great size, over 1½ inch across, broad white paste, black body colour. Truss very strong, containing nine flowers.

Cineraria Prince of Wales (James).—A rosy crimson self, flower very large and rich in colour, broad rounded florets.

Cinerarias Lottie Williamson and Lord Wolseley (James).—Previously arranged.

Cineraria Kate Williamson (James).—A rich dark blue self, slightly reddish at the base of the florets. Very distinct.

AT a general meeting of the ROYAL HORTICULTURAL SOCIETY, held last Tuesday, William Payne, Esq., F.R.H.S., in the chair, the following candidates were unanimously elected Fellows—viz., the Hon. Mrs. Bagwell, Henry Spring Bean, Rev. Albert Dearn, Theodore Duka, Mrs. Duka, Thomas Farmer Hall, A. J. Hollington, and William Jenkins.

— THE Committee appointed at the DAFFODIL CONFERENCE to consider the desirability of renaming the garden varieties of Narcissus in accordance with resolution passed, met on Wednesday, the 2nd inst., at South Kensington, and entered into the matter fully. The result was that popular names were adopted for all the varieties shown, and Mr. J. G. Baker was entrusted with the task of formulating the decision of the Committee, which will be ultimately published.

— MANY readers will learn with much regret that MR. EDWARD MILNER, the noted landscape gardener, died at Norwood on the 26th ult. During the past two or three years Mr. Milner has been engaged as principal of the Crystal Palace School of Gardening; but previously he had performed much excellent work in reorganising old gardens, designing and laying out new ones in all parts of England, but especially in the midland and northern counties. On the Continent also numerous gardens bear testimony to his skill and good taste.

— MR. C. GREEN writes:—"It may be interesting to the readers of the Journal to know there is a very fine specimen of RHODODENDRON NUTTALII at Daylesford Gardens, imported, we believe, from its native habitat, the Himalayan Mountains. The plant is in every way magnificent. It is 12 to 13 feet in height, and at the present time is bearing

forty noble trusses of its magnificent blooms in whorls of from five to seven. Each of its large bell-shaped flowers would hold half a pint of water. We believe there is some difficulty in flowering this variety, but it is known to have flowered at Daylesford abundantly every spring. It makes a grand conservatory plant, and ought to be in every collection."

— THE ORCHARD HOUSES in Mr. Rivers' nursery at Sawbridgeworth are now extremely beautiful, fruit trees of all kinds, that are so successfully grown, being densely covered with blossom; fine crops of fruit will follow in due time, failures being practically unknown at Sawbridgeworth.

— Two fine specimens of the beautiful RHODODENDRON AUCKLANDI are now flowering in Mr. Major's collection at Cromwell House, Croydon. Several trusses are expanded, each consisting of six large fragrant campanulate flowers, one before us being 5 inches in diameter and exceedingly handsome.

— AMONGST the numerous handbooks announced by the Committee of the International Health Exhibition Committee is one entitled the "FRUITS OF ALL COUNTRIES," by Mr. W. T. Thiselton Dyer, M.A., which is likely to possess considerable interest.

— CHIONODOXA NANA and C. SARDENSIS, though pretty, will not bear comparison with the true "Snow Glory," C. Lucilike, for the flowers are much smaller and less showy. C. sardensis appears to differ very slightly from the better known species, except in the flowers being smaller and the blue colour running through the petals to the centre of the flower. C. nana is similar, but it is probable that under good cultivation both will improve.

— GARDENING APPOINTMENTS.—Mr. William Cooper, late foreman at Sandbeck Park, Rotherham, has been appointed gardener to the Earl of Meath, Kilruddery, Bray; Mr. Edwin Beckett, late gardener to J. P. Currie, Esq., Sandown House, Esher, Surrey, has been appointed gardener to H. Hucks Gibbs, Esq., Aldenham Park, Elstree, Herts.

— THE Ealing, Acton, and Hanwell Horticultural Society's twentieth ANNUAL SHOW will be held in the grounds of the Manor House, Ealing, on Wednesday, July 9th, and the seventh Autumn Show at the Drill Hall, Ealing Dean, on November 5th. At both Exhibitions, in addition to the numerous prizes offered by the Society, many valuable special prizes are contributed by friends of the Society in the neighbourhood.

— ALL admire the charming PRIMULA ROSEA, but some cultivators have experienced a difficulty in growing it successfully, and this is generally due to keeping it too dry. Upon the rockwork it will grow and flower, but how great a difference there is between plants in such positions and those in a semi-marsh, but where there is no offensive stagnation. This indeed is the main secret of its culture—keeping the roots cool and moist; the growth is then much more vigorous, the foliage of a fresh healthy green colour, the flowers are larger, and the rosy hue richer.

— "E. R." writes:—"Permit me to give a word of praise to the beautiful HYACINTH L'OBELISQUE, which of a large collection has pleased me more than all. The colour of the well-formed bells is a delicate creamy yellow, very pure; the fragrance is quite distinct and most agreeable; the spike massive and well-proportioned. One very fine bulb has now four spikes expanded, one of great size, and the others but slightly smaller, and the plant has been the admiration of all my friends. Can any of your readers tell me anything as to the origin of the variety?"

— BEFORE us are a number of FANCY PRIMROSES grown by Mr. Cannell at Swanley, which for size, substance, and diversity of colour we have not seen excelled. All the colours usually seen in self flowers appear to be represented, while many of the blooms are beautifully mottled, flaked, and marbled with white on a crimson ground. We also find the quaint Galligaskins amongst them, and a laced Polyanthus remarkably bright and with clearly defined margins. Such Primroses as these referred to could not fail to be appreciated in gardens in which these favourite flowers are cherished.

— AT the Daffodil Conference last week two of the most distinct and beautiful varieties were NARCISSUS INCOMPARABILIS ALBUS MILNERI, and VOLUTUS J. G. BAKER. The first is a particularly handsome

flower, well-proportioned, the petals broad, rounded, and pale creamy white in colour; the crown is much expanded, of a rich orange shade, but lighter at the base. The other is one of the Pseudo-Narcissus type, of a clear delicate lemon tint, the crown large, even, with the margin slightly reflexed, the petals being of equal length and the same colour. Another very effective variety that is worth growing extensively is N. incomparabilis pallidus aurantiacus, which has neatly formed flowers, the petals pure white, the crown of moderate size, but of a particularly bright orange colour, which contrasts very markedly with the other portion of the flower. For cutting and decorative purposes generally it would be most useful. Amongst the varieties of N. poeticus none excels the beautifully formed ornatus, the flowers being most symmetrical.

— "THE SCIENCE MONTHLY" for April contains a very interesting article upon "The Odour of Plants," in which the subject is exhaustively treated, special reference being made to the nature of the odours and their services to the plants.

— WE have received from Mr. B. S. Williams, Holloway, a box of LACED POLYANTHUSES, the produce, we presume, of flowers raised from seed. As such they are excellent, and although some of them may be faulty, as judged by the exacting rules of the florist, they are as good as can be desired for garden decoration, and for one Polyanthus specialist there are five hundred growers and admirers of these flowers which render beds and borders bright and cheerful at this period of the year.

— AT the ordinary meeting of the ROYAL METEOROLOGICAL SOCIETY, to be held at 25, Great George Street, Westminster, on Wednesday, the 16th instant, at 7 P.M., the following papers will be read:—"On the Origin and Course of the Squall which capsized H.M.S. *Eurydice*, March 24th, 1878;" by the Hon. Ralph Abercromby, F.R.Met.Soc. "Waterspouts and their Formation;" by Capt. J. W. C. Martyr. "The Weather Forecasts for October, November, and December, 1883;" by Cuthbert E. Peek, M.A., F.R.Met.Soc. "On certain Effects which may have been produced in the Atmosphere by Floating Particles of Volcanic Matter from the Eruptions of Krakatoa and Mount St. Augustin;" by William F. Stanley, F.R.Met.Soc., F.G.S.

— THE SHROPSHIRE HORTICULTURAL SOCIETY still holds a foremost rank amongst provincial organisations. By the balance sheet of last year we find that the income of the Society for 1883 was £2200, and the expenditure £1600, leaving a profit on the year of £600. The Society has spent over £1000 in town improvements, such as new gates, handsome band stand, &c., and still has a reserve fund of nearly £2000. This is the work of only nine years. As an instance of the popularity of this Show, we note that in addition to cheap tickets sold previous to the day amounting to £396, no less a sum than £1055 was taken at the turnstiles on the second day alone. Nearly 45,000 persons were present both days. The Show this year will be held on August 20th and 21st.

— A CORRESPONDENT sends the following cutting:—"In certain portions of the south-west United States is a shrub which grows abundantly, and particularly on the borders of the Colorado Desert, where it is so luxuriant that it acts as a barrier to the drifting sand. This is the CREOSOTE PLANT (*LARREA MEXICANA*), and is a sure sign of a barren soil, for it flourishes where nothing else will, and although it gives the scenery a beautiful verdant appearance it has such a strong repulsive odour of creosote that no animal will touch it. Even for fuel it is almost useless, as it can scarcely be made to burn. The odour is due to a resinous matter, of the value of which the Pimos Indians have long been aware, as they collect and form it into balls, which they kick before them as they journey from one point to the other of the trail. This exudation has been shown by Mr. Stillman of California to be identical with the gum-lac of India, and he believes that the lac is secreted by the insect found in it, and that it is not, as usually supposed, the result of an exudation of the plant caused by the punctures of the insect. The Entomologist of the Bureau of Agriculture does not consider that the insect itself is the same as the *Carteria lacca*, the incrustations of lac on the creosote plant not being so thick as that produced by *C. lacca*; but as it presents a similar system of large and complicated excreting organs he has named it *C. larrea*."

— THE schedule of the NATIONAL CHRYSANTHEMUM SOCIETY for 1884 is now issued, and in addition to full particulars as to the classes and prizes at the thirty-eighth Exhibition, to be held in the

Royal Aquarium, Westminster, November 12th and 13th, it contains lists of the officers, honorary members, and subscribers, together with the names of the prizetakers at the previous show and the balance sheet for the past year. From the latter we learn that the Society has a balance in hand of 4s. 8d., the amount of reserve fund invested in consuls up to December, 1883, being £61 10s. 11d. The prizes are of the usual liberal character, all the classes being open to exhibitors from all parts of England, except nine, termed Metropolitan Classes, which are confined to persons residing within three miles and a half of Shoreditch Church. The winner of any prize in the Chrysanthemum classes is entitled, on application to the Hon. Secretary, to receive a specially designed certificate recording his success, the cost of which will be defrayed by a fund instituted for the purpose. The leading class is that for forty-eight blooms, twenty-four incurved and twenty-four Japanese, the first prize for which is £15, £10 being given by the Society, and £5 by Mr. N. Davis of Camberwell. The other prizes in this class are £7 and £4. It should be added that the Society undertakes to defray a portion of the cost of carriage of the plants.

MANURES FOR PLANTS IN POTS.

It may be roughly assumed that there are two classes of cultivators who err in the matter of applying manure to plants in pots. One do not as a rule apply any manure after the plants have been potted; the other begins to supply with manurial solutions long before the plants require it, and continues to do so as long as the plants are able to bear up against the treatment. These are extreme instances; but there are many who do not go to such extremes, who yet fail to grasp the true reason for the application of manure with water. There are, it is true, soils so poor in quality, so deficient naturally in the constituents of plant food, and so incapable of retaining these when applied, that it becomes necessary to add manurial agents with the water at a much earlier period after potting than is necessary or even wise in the case of other soils. Therefore no hard-and-fast line can be laid down on this matter; and hence we find one writer advising the application of liquid manure when the roots begin forming round the outside of the ball, while another tells us to wait till the roots have become much more numerous.

The mode of potting the plants must not be overlooked as an agent in timing the first necessity for liquid manure. Firm potting as a rule and the employment of small pots give better results all round than an opposite practice. A comparatively small pot filled firmly with soil has the plant food more concentrated and lasts longer than if the soil were loosely placed in the pots. However, in most classes of soil the time arrives sooner or later when manure must be applied. It then remains to consider the best manurial agents and the best mode of applying them. Many gardeners have their favourite mixture, to which they cling with unswerving fidelity. Sheep, deer, cow or horse manure, singly or in mixture, are all employed in the preparation of liquid manure. Soot and guano are occasionally used, but often with a feeling of uncertainty.

The reason why manure has to be employed for plants in pots is simply because the roots have extracted all or nearly all of certain elements necessary to the health of the plant, and any extra applications of manure must be given in order to meet these wants. Nitrogen is commonly the first element to be used up; hence it is that occasional pinches of Peruvian guano, sooty water, or a little nitrate of soda or sulphate of ammonia, cause the plant to assume fresh vigour and life. These not only supply a want, but by some unknown law enable the plant to appropriate other plant foods, which before they were incapable of doing. Liquid manures from animal excreta act in much the same manner as those already mentioned. Of the very necessary though small potassic elements they are all deficient, and after a time flowering plants fail to respond to manurial agents not containing this element.

Surface applications of mineral manures is the cleanest and most generally efficacious mode of furnishing plant food to the soil. An effective and cheap dressing may be composed of superphosphate of lime 4 lbs., chloride of potash 3 lbs., and sulphate of ammonia 2½ lbs. As much of this mixture as will lie on a shilling applied to flowering plants once a week throughout the summer months will give the best results. Should there appear to be a tendency to flower too much at the expense of growth apply sulphate of ammonia alone (or guano will do), for two weeks or so, and fresh growth will be excited at once. For Ferns nothing better than guano and soot dissolved in the water can be given, so also for fine-foliage plants generally, though an occasional pinch of the above mixture will be of advantage.

Irregular watering will stultify the benefit derivable from any kind of manure.—R. P. BROTHERSTON.

BROWALLIA JAMESONI.

OLD favourite plants are occasionally re-introduced to notice by nurserymen or amateurs, and those who thus rescue really meritorious plants from the neglect into which they have been allowed to fall deserve as much public credit as the first introducers. In the past few years many such forgotten plants have been brought before the Royal Horticultural Society at Kensington, and the subject of the present note is one of the most remarkable and handsome of these restored favourites.

Thirty-six years ago Messrs. Veitch & Son introduced *Browallia Jamesoni* from Peru, where it had been found by their collector growing in wood at an elevation of 6000 feet above sea level. It attracted some attention then, and was figured in one or two botanical works, but seems

Fig. 69.—*Browallia Jamesoni*.

to have escaped the attention of the general cultivator, and, except in a few large collections, the plant is now rarely seen. When, therefore, Messrs. H. Cannell & Son exhibited a specimen at the Royal Horticultural Society's meeting, March 11th of the present year, it was quite a welcome surprise to many, and a certificate was granted for it without any hesitation.

As we have previously stated, the plant is suggestive of *Rondeletia speciosa* in habit and the form of flowers, and requires training to a few stakes, allowing the heads of flowers to hang slightly downwards, as they are seen to better advantage in this way (fig. 69). The corollas are about an inch across the mouth, very bright orange in colour, slightly lighter in the centre, and are borne in close heads at the extremity of the branches.

Any light rich soil suits the plant, which thrives in a greenhouse temperature with very little care.

EUCHARIS AMAZONICA.

THERE is scarcely a stove house now that has not the *Eucharis* as one of its inhabitants. Still, judging from the inquiries often made, it would appear that it is difficult to flower. As we have been very successful in growing and flowering this lovely plant we shall as briefly as possible describe our mode of treatment. To begin with, the bulbs must be a good size, say about 8 inches in circumference and thoroughly well matured before they can be expected to flower, so therefore we must turn to the growing treatment first.

Soil.—After trying various composts we find a mixture of three parts of good fibrous loam, with one part of half-decomposed cow dung suit it well. When the roots are not so numerous as we would like, as is often the case with young bulbs, instead of the cow dung we add the same quantity of leaf mould. This appears to encourage the young bulbs to make roots rapidly.

Pots.—The size of pot is a matter of taste, as the plants thrive in almost any size, from a 6-inch pot upwards. When they are grown for cut flowers we prefer 12-inch pots, with from nine to eleven bulbs in a pot. In every size of pot the drainage is ample, never less than 3½ inches of crocks in the largest size.

Potting.—We pot our *Eucharis* annually some time in February, turn them out on to the potting bench, break up the ball, disentangle the roots, take off the offsets, doing all this very carefully, as the roots are easily damaged, potting all again in the mixture mentioned above, spreading the roots as much as possible amongst the soil, allowing one-half of the bulb to remain above the surface, pressing the compost moderately firm. Some growers advocate the root-bound system to cause them to flower, but we are averse to this method of treatment for the following reasons. First, when allowed to remain undisturbed, instead of growing and preparing the bulb to flower again they form offsets; secondly, they descend or become buried among the soil; the third fault is the worst, the drainage gets out of order.

General Culture.—After the potting process they are plunged into the stove house bed, which gives a temperature of 75°, the heat of the house being 65°, letting it run up to 80° as the season advances. Very little water is given for some time—a dewing daily—until it can be seen that growth has fairly commenced. After this has taken place water is more freely given. As soon as it can be ascertained that the roots are plentiful liquid manure is given (sheep's droppings is our favourite), commencing with it rather weak for a time. As soon as they appear to have made their growth water is again gradually withheld, at the same time raising them out of the bed. Here they stand for a few days, when they are removed to a cooler structure with a temperature of 50°. A vinery where the fruit has been cut suits them well when resting. Water is given very sparingly, only as much as will keep the leaves erect. The resting period lasts from two to three months. After this they are returned to their former quarters, being then thoroughly soaked with tepid water, and thus treated we find them flower very well. We have *Eucharis candida* in flower at the present time, having received the above treatment.—J. J. C.

MAGNOLIA CONSPICUA.

CALLING at Mr. John Fraser's nursery at Leyton, Essex, recently, my attention was directed to a very fine specimen of the showy *Magnolia conspicua*, which was flowering most profusely against the front of the office. It is much to be regretted that this showy early-flowering species of *Magnolia* is not more generally met with in gardens. Extensive preparations had been made previous to my visit by Mr. Fraser to secure a large stock of this by layering. As this plant was covering a large extent of wall and had attained a great height, layering in the ordinary way could not be easily practised. To overcome this difficulty a framework of wood forming several stages was erected. On each of these stages were pots filled with soil, plunged in moss. The shoots were then layered in the usual way by conducting these through the soil in the pots. By adopting this ingenious method Mr. Fraser will no doubt secure a large stock of this showy *Magnolia*.

In one of the houses in the same nursery I also saw a large collection in flower of a very superior strain of *Cyclamens*. The collection embraced many hundreds of very healthy and well-grown specimens. These, I was informed, were grown for affording seed—a great speciality in this establishment.—S.

WATERING, SHADING, AND VENTILATING ORCHIDS.

IF Orchids are to be grown well the cultural matters which form the heading of these notes must each be carefully attended to. The different aspects, construction of the house, ventilation, and heating

arrangements all have a bearing on the subject. The following remarks are intended principally for the benefit of younger gardeners, some of whom think there is a mystery attached to Orchid-growing, though the mystery is easily solved by common sense and close attention. If they notice the season of growth and of rest they will find no difficulty in growing the majority of Orchids, but a knowledge of geography and meteorology of the different countries the Orchids inhabit will assist considerably in their culture.

I will first give a few remarks on the management of "cool Orchids." As to the proper aspect of the house for these, there is a difference of opinion. Some prefer the "north" lean-to, others the span-roof or three-quarter span facing north. I suspect each have their good qualities, and have served those who have recommended them. The north lean-to certainly has advantages in the south of England, whilst in the north, and especially around the large manufacturing towns, Manchester for instance, the span-roof running north and south would be the best. I have grown good cool Orchids in the south of England in a span-roof house, but it was rather of heavy build. The ends were north and south, but it was during the autumn, winter, and spring that the plants succeeded best; and we often longed for a north lean-to during the summer, as they had to be continually shaded. In the winter the little sun that we have certainly does not reach the north lean-to, whilst if the plants were grown in a span-roof house they certainly would receive the benefit of it, and the three-quarter span would have a share. So in the south, a three-quarter span facing north is recommended, and a span-roof in the north.

Ventilation must be regulated, so that the plants are not exposed to a draught. A close atmosphere is fatal to the well-doing of cool Orchids. Shading must be attended to, so as to keep off direct sunshine during the spring, summer, and early autumn months; but when there is no direct sunshine on the house remove the shading at once. The ends and sides (if there are side lights) should be attended to when required. As to watering, give sufficient to *Odontoglossums* of the *O. crispum* type and *Masdevallias* to keep the sphagnum in a healthy growing condition. If the sphagnum is healthy the Orchids will generally be the same. A good guide as to the time to supply water is when the tips of the sphagnum have a white tinge, but are not parched. Water the plants in the afternoon during the summer, and morning during the winter. Keep abundance of moisture about the house during favourable weather, and syringe between the pots twice a-day, but on wet days or during severe weather in winter do not have much moisture in the house. If other Orchids are grown in the cool house they must be treated accordingly. Some of the *Oncidiums* are grown in this house; they will only require a plentiful supply of water whilst in active growth, but when at rest must by no means be allowed to get dry. Cool Orchids require no artificial heat during the summer, and during the winter only when the temperature falls below 45° or during wet close weather, when a little heat in the pipes will keep the atmosphere in a suitable condition.

Occupants of the *Cattleya* or intermediate house prefer a warmer and drier atmosphere than cool Orchids. The shading must be according to the aspect or build of the house, and a good guide is not to expose the plants to direct sunshine during the spring and summer, ventilating whenever it can be done safely. If only *Cattleyas* are grown in this house they will need less shading than when the collection is a mixed one, and in the latter case it will be advantageous to have the shading in two parts, so that it can be drawn up earlier over the *Cattleyas*. If the house is in two divisions so much the better, as the *Cattleyas* or other Orchids that succeed with the same treatment may be grown in one division. The temperature best suited for this house is 55° as a minimum during the winter, with a proportionate rise during the spring and summer. *Cattleyas* do not require so much water at the roots as the majority of Orchids. Large specimens only need a supply once or twice a week during the growing season. Small plants require more frequent attention; they must not be kept too wet or too dry. Whilst at rest *Cattleyas* require very little water, only sufficient to prevent shrivelling. *Odontoglossum vexillarium* and *O. Phalaenopsis* succeed well in this house, but must be placed at the shaded end. These *Odontoglossums* must never be allowed to become dry at any season. On the other hand, those of the *O. grande* and *O. Insleyi* type must be kept quite dry after they have made their growth. Some of the *Cypripediums* succeed well here. These must never be allowed to become quite dry whilst at rest. The majority of the *Oncidiums* succeed best in this house, and require a plentiful supply when in growth, when at rest only sufficient to keep them from suffering; and many other Orchids too numerous to mention succeed here. The *Cattleya* house or intermediate house is a very good one in which to rest and flower the majority of *Dendrobiums*, but whilst they are making their growth they succeed in a warmer and more moist house.

The occupants of the East India house or warm stove comprise *Angræcums*, some of the *Cypripediums*, *Dendrobiums* whilst making

their growth, *Odontoglossum Roezlii*, *Phalænopsis*, *Saccolabiums*, *Vandas*, &c. If the seasons of growth and rest are watched the watering of these plants is soon mastered. The *Angræcums* require a plentiful supply when in growth, but must never be allowed to become too dry whilst at rest. This applies to the majority of Orchids except *Dendrobiums*, which like to be quite moist when in growth, but must have a thorough rest. For instance, if *Dendrobium densiflorum* and *O. thysiflorum* are kept moist whilst at rest they will fail to bloom. The *Cypripediums* in this house will require a plentiful supply of water when in full growth. Abundance of moisture is needed during the growing season, and shade from direct sunshine. The temperature best suited for this house is 60° to 65° as a minimum during the winter, with a proportionate rise during the spring and

February, 1883, it grew freely and produced many flowering buds from the axils of the leaves on flower stalks about 1½ inch long. The buds were very small, hardly so large as hemp seeds, and it continued to produce them through the summer, when it was removed into a cool greenhouse, but none of the buds ever swelled above the size I have mentioned, and one after another fell off. I shall be glad to know if others have found the same difficulty in blooming this plant, and if not, what system of cultivation they pursued to obtain a more satisfactory result.—AN AMATEUR.

ROYAL CALEDONIAN HORTICULTURAL SOCIETY.

APRIL 2ND AND 3RD.

THE spring Show of this thriving Society was held in the large Waverley Market, Edinburgh. The prizes offered were divided into seven sections, five

Fig. 70.—AMARYLLIS MARS. (See page 278.)

summer. Each house is benefited by 5° extra fire heat by day when required, but the temperature should never be allowed to rise too high by fire heat, as it causes the plants or compost to become dry; besides, it is not healthy for the plants.—A GROWER.

CRINODENDRON HOOKERIANUM.

CAN any of your correspondents tell me anything of their experience in growing the plant *Crinodendron Hookerianum*, otherwise *Tricuspidaria hexapetala*, described on page 98, vol. vi., of your Journal? I purchased a small plant from Messrs. Veitch as one of their novelties in November, 1881. It showed signs of suffering in a cool greenhouse in the winter following, but being placed in a vinery when the Vines were forced in

of these being for gardeners and amateurs, the remaining two for nurserymen. The first five were for plants, Hyacinths, &c., cut flowers, fruits, and vegetables. The two classes set apart for nurserymen were for plants Hyacinths, and cut flowers.

PLANTS.—One of the main features in the plant classes were the prizes for a table of plants 20 feet long by 5 feet wide, arranged for effect. Only two competitors entered, Mr. Grossart, gardener to J. Buchanan, Esq., Oswald Road, being placed first, many well-flowered Orchids being represented, such as *Dendrobium Wardianum*, *D. Jamesianum*, *D. thysiflorum*, *Odontoglossum Alexandræ* and *cirrhum*, *Cattleya Trianae*, &c., with a few Palms and other fine-foliage plants, making a bright arrangement. The second table, from Mr. A. Paul, Gilmore Place, was rendered less attractive by the formality of the arrangement; some good Orchids were, however, also shown, and a number of small plants of *Primula nivea* were very pretty.

Prizes were also offered for tables of spring-flowering plants. Mr. W. Begg, Wardie Lodge, Granton, was first with a very choice selection, *Fritillaria meleagris alba* and *Trillium grandiflorum* being especially noteworthy. Mr. C. Smith, Restalrig House, was second. For twenty forced plants in bloom Mr. Priest, gardener to the Marquis of Lothian, Newbattle Abbey, was first, and Mr. McClure, Trinity Grove, second. The Azaleas were large and finely flowered, Mr. Patterson, gardener to J. Syme, Esq., Millbank, being first for four plants with round-headed densely bloomed specimens, and Mr. Paul second. The other specimens were small, but the four in 8-inch pots from Mr. Patterson were beautiful little globes of bloom. The same cultivator gained the premier position for six stove and greenhouse plants in flower with two good Azaleas, three Heaths, and an *Anthurium Schertzerianum*. Mr. Paul was again second. Greenhouse *Rhododendrons* were small and hardly worthy of note. For four *Rhododendrons* (hardy) Mr. Grieve, gardener to Miss Falconer, Faleon Hall, was first with large well-bloomed specimens. Heaths were, like the *Rhododendrons*, in small sizes. Orchids were not numerous, but some large specimens were set up. For six distinct sorts two collections were staged, one from Mr. Paul, and the other from Mr. Grossart, equal first prizes being awarded to them. Mr. Paul had a very large plant of *Caelogyne cristata*, a grand piece of *Cymbidium eburneum* with about thirty open flowers, C. Lowi with a dozen spikes, a fine form of *Cattleya Trianae*, *Dendrobium densiflorum*, and *D. nobile*. Mr. Grossart's best plants were *Dendrobium Wardianum*, *Cymbidium Lowi*, a fine variety, and *Ada aurantiaca*. For three plants Mr. W. Dougal, gardener to W. Sanderson, Esq., Talbot House, was first, having as one of the trio the rarely seen *Odontoglossum Phalaenopsis*. Mr. A. Fraser, Canonmills Lodge, was second. For one plant Mr. Patterson, Millbank, was first with *Dendrobium nobile*.

Ferns were not large, the best being from Mr. McKinnon, gardener to Viscount Melville, Melville Castle. Mr. Paul showed three fair *Gleichenias*, for which the first prize was awarded. Fine-foliage plants were small, and do not call for remark.

HYACINTHS.—A table of these with massive spikes attracted much attention. For twelve plants Mr. Pearson, gardener to Lady Lucy Dundas, Beechwood, was first with strong even plants, King of the Blues, Sultan, Lord Derby, and Koh-i-Noor being especially fine. Mr. Sims, gardener to C. Kindsay, Esq., Ridge Park, Lanark, was a close second with an extra fine Koh-i-Noor in his lot; and Mr. McLure, Trinity Grove, third. Mr. Laurie, gardener to Mr. Mackay, Inveralmond House, Cramond, was first for eight, all good, Mr. Sims being again second, and Mr. McLure third; for six Hyacinths Mr. Laurie was also first. For six for amateurs Mr. Robert Stewart, Haddington, worthily occupied first position, Mr. A. Whitelaw, Musselburgh, being second. Tulips made a great display. For six pots Mr. Begg, Wardie Lodge, took the first place, Mr. R. Grossart being second. Mr. R. Gibson, Woolmet, Dalkeith, was first for six pots, and Mr. Cameron, gardener to the Rev. Ch. Dornele, Cargillfield, second. For six *Polyanthus Narcissus* Mr. S. Graham, Kilrock Lodge, was first, and Mr. Pearson second. Mr. Grossart was the only exhibitor of six pots of garden *Narcissus*, and obtained the first prize. The *Cinerarias*, *Primulas*, *Hoteias*, hardy Azaleas, &c., were all fairly well represented. Some good *Deutzias* were set up, Mr. Grieve, Falcon Hall, having the best. *Polyanthuses*, *Primroses*, and *Anriculas* were of poor quality. Lily of the Valley was fine, Mr. J. Bald, Cannon House, being first for three plants, and Mr. R. Johnston, Woolmet, first for one. The *Mignonette* was also extra fine; Mr. Greig, Graigend Park, Liberton, being first for two dwarf plants, and Mr. Richardson, Morningside, first for two standards. For six Roses Mr. Patterson was first with medium-sized specimens with fine blooms, and Mr. McIntosh, Boston House, second with rather tall Tea Roses.

NURSERYMEN'S PLANTS.—A table of plants 40 feet long and 10 feet wide was the principal class in this section, and Messrs. Ireland & Thomson, Cragleith Nurseries, took the premier position with one of the richest displays ever staged in Edinburgh. Fine-foliage plants were very sparingly employed, only a few Palms, Azaleas, *Rhododendrons*, *Azalea mollis* forming the foundation of the group, choice flowering Orchids being lavishly employed, *Cattleya Trianae*, *C. amethystoglossa*, *Odontoglossum Alexandrae hybrida*, *O. Alexandrae* in variety, *Lycastes*, *Dendrobiums*, thyrses-flowered, wreathed in spikes and racemose, *Cypripediums* in variety, and *Oncidium Rogersi* being the chief plants. Messrs. T. Methven & Sons, Leith Walk Nurseries, were second; and Messrs. B. Laird & Sons, Parkhill, third with arrangements chiefly composed of ordinary decorative flowering and fine-foliage plants. The last-named firm took first prize for four greenhouse *Rhododendrons* with large specimens; for twelve hardy *Rhododendrons*, also large and fine; for six Palms; for twenty-four Hyacinths, finely developed; for bride's bouquet; and for six buttonhole bouquets. In addition to the first prize above noted Messrs. Ireland & Thomson were first for twelve hardy *Rhododendrons* in 9-inch pots, for three *Crotons* and three *Dracenas*, for twelve table plants, for six new or rare plants, and for a collection of cut stove or greenhouse plants. Messrs. Methven & Son were first for twelve *Coniferae*, Messrs. Cunningham, Fraser, & Co. being second, the latter firm taking first place for twenty hardy plants. Mr. Brysen, Helensburgh, had the best twelve cut Roses, W. Gordon & Son being first for twelve *Ma échal Niel*, while Messrs. Todd & Co., Edinburgh, had the best hand bouquet.

CUT BLOOMS.—These were staged in Messrs. Mackenzie & Moncur's conservatory, of which note is made further on. The Roses formed a large exhibition and generally fine. For twenty-four Mr. Jas. Walker, gardener to J. M. Richard, Esq., Clarendon, Linlithgow, was first with neat good-sized buds, mostly Teas. Mr. Bowman, gardener to Lord Deas, Pittendreich, Lasswade, was a very close second indeed; and Mr. McIntosh third. For twelve Mr. Shiach, gardener to J. MacKnight, Esq., Cranford, Lauriston Castle, was first with a very fine lot of buds; Mr. Cumming, gardener to Miss Ivory, St. Royne, second. For twelve *Gloire de Dijon* Mr. Walker took the first place with large globular buds. For the same number of *Maréchal Niel* Mr. Pearson showed by far the grandest blooms staged, these being large and well coloured; Mr. Dow, gardener to Sir D. Baird, Newbyth, was a good second. *Camellias* were largely shown. The prizes for twelve bunches of flowers of stove or greenhouse plants brought good competition. Mr. Priest was first, showing *Dendrobium fimbriatum oculatum*, *D. densiflorum*, *Vandas*, *Lycaste Skinneri*, &c., with *Clematis indivisa lobata*, fine, and *Cantua dependens*. Mr. McIndoe, Hatton Hall, Guisborough, Yorks, was a close second, *Rhododendron Veitchii* being fine. Some of the bouquets

were beautiful, the first-prize table and hand bouquets, each from Mr. Grossart, being especially fine; Mr. McLure, Trinity Grove, was a good second for each of these.

FRUIT.—This was fairly well shown, a large number of well-kept Apples being brought together. Three Pine Apples were staged, Mr. Johnston, Glamis Castle, being first; and Mr. McIntyre, The Glen, second. For two bunches of Black Grapes Mr. McKinnon, Melville Castle, was first with remarkably well-kept Alicantes, and Mr. McIndoe second with Lady Downe's. Mr. Dow, Newbyth, was first for thirty Strawberries, President large and well coloured, and for six pots of Strawberries. For twenty-four kitchen Apples Mr. Potter, Seacliffe, North Berwick, was first, and Mr. Bowman second. For twenty-four dessert Apples Mr. Brunton, Gilmerton, Drem, was first; and Mr. McKelvie, Broxmouth Park, Dunbar, second. To Mr. Brunton, Gilmerton, a special award was made for a collection of sixty-two sorts Apples. The best varieties in the prize collection were King of the Pippins, Blenheim Pippin, and Cellini. In the other collections were good examples of Fearn's Pippin, Court-Pendu-Plat, Winter Strawberry, Dutch Mignonne, Cornish Aromatic, Stone Pippin, Ribston Pippin. The best examples of kitchen kinds were Warner's King, Mère de Ménage, Allanbank Seedling, Gloria Mundi, Dumelow's Seedling, Beauty of Kent, Ecklinville Seedling, Yorkshire Greening, and Northern Greening. In Mr. Brunton's collection were some notable kinds, as also in another collection of fifty sorts without indication from whence they came, and to which a special prize was also awarded. They deserved a special note. The prize for twenty-four Pears brought fruit of poor quality.

VEGETABLES.—These were very fine and fairly well represented as to quantity. For a collection of twelve kinds Mr. Potter, Seacliffe, showed an excellent lot for the first prize. These comprised good Leeks, Cabbages, Rhubarb, extra fine Broccoli and Brussels Sprouts, French Beans, Potatoes, Carrots, Mushrooms, last season's Onions, Peas, Seakale, and Carrots. Mr. Bowman was a good second, and Mr. Robertson, Hartrigge, Jedburgh, third. For six Leeks Mr. Potter was again first with extra fine specimens. Mr. Smith, Restalrig House, had the best six Broccoli, Mr. Bowman the best Seakale, and Mr. Stewart, Newhaven Road, the best collection of salads.

MISCELLANEOUS EXHIBITS.—Amongst these were the fine table of mixed plants from Messrs. Godden & Son, a collection of plants from the Lawson Nursery Co., a pretty arrangement of ordinary market plants from Messrs. Todd & Co., who also showed a fine wreath and crop of cut flowers. Messrs. Mackenzie & Moncur, Upper Grove Place, showed a conservatory 30 feet by 18 feet, with ventilating gearing on a new patent principle which they have introduced. Many ventilators having been wrenched from their places during the past windy weather this system has been devised to obviate this in the future. The motive power is given by an endless screw to a toothed pinion on the ventilating shaft. At equal distances along the shaft toothed pinions are attached, which lift or shut the ventilator at pleasure by acting on a toothed segment bar fastened to the ventilator. It is considered that no wind will be able to move a ventilator, whether open or shut, with this arrangement fitted on them.

It only remains to say that this was the finest spring Show ever held by the Society since they began holding them in 1855 with a prize list of £22, but this one of 1884 amounts to £350. The Exhibition was opened by one of the municipal officials, and was throughout the two days crowded with visitors, excursion trains being run from many towns.

CENTRADENIA ROSEA.

THIS beautiful plant is of easy culture, and ought to be grown by every one who can command a minimum temperature of 50° through the winter months. Coming into flower, as it does, about the middle of February and lasting well into April, it enlivens stoves and warm conservatories, its rosy white flowers and long narrow leaves, green on the upper surface and deep red on the under surface, rendering the plant very striking; moreover, it has a graceful drooping habit, of dwarfish growth, which makes it most suitable for the dinner-table, and other decorative purposes. It will flower as freely in 5-inch pots as it will in 8 or 10-inch pots.

These Mexican *Melastomads* should be propagated at once by inserting cuttings of half-ripened shoots in a compost of sandy loam and peat in well-drained pots, plunging them in a brisk bottom heat of about 75° to 80°. The temperature of the propagating pit or house should be the same when the cuttings are well rooted, which will be in three weeks; they should then be potted singly into 2½-inch pots, shading and keeping them in a close moist house until they are well rooted into the new soil, when they may be removed to a lighter and more airy house and placed on the shelves near the glass. When they have filled these pots with roots they should be transferred into 4-inch pots, using some good turfy loam and peat, with a dash of sand. The pots should be well drained, for this *Centradenia* is a moisture-loving plant. When they again become root-bound they should be shifted into 6 or 8-inch pots, in which they may be allowed to bloom, or if thought desirable they may be grown and flowered in larger pots, but 6 and 8-inch pots we find the most useful for all ordinary purposes.—G. J. WARREN, *Balcombe Place, Sussex*.

THE "DENNIS" SYSTEM OF PATENT GLAZING.

AMONGST the various exhibits at the Building Trades Exhibition at the Agricultural Hall, London, a glass structure glazed on a new system has attracted attention. It is not another of the many examples of glazing without putty, for putty is used, but is quite protected from the weather. The method is the invention of Mr. T. H. P. Dennis of Chelmsford, who, although only now introducing it to the public, has had a structure so glazed on trial for many months with the object of testing its merits or noting its faults. The result of the trial is that he feels fully justified in bringing it out as a system of great practical usefulness, and by which his reputation will be sustained.

As will be seen by the diagrams, the glass is pressed against the sash-

bars by cork cams, or rather against the putty between the glass and under side of the bar. It is thus both firm and watertight, while the putty is completely protected from the weather. Glazing is done from the inside of the house—in fact, it cannot be done from the outside, and is so simple that any ordinarily intelligent workman can fix it, while squares can be removed from and placed in any part of the roof that may from accidents need repairing. But although putty is used, and is

Fig. 71.—Wood Sash-bar with Putty.

Fig. 72.—Wrought-iron Sash-bar with Putty.

considered an advantage, the glass can be fixed without putty if preferred. The system is quite distinct from other methods of glazing, and appears to possess the merits of simplicity with efficiency. The references to the diagrams are—A, sash-bar; B, glass; C, cork cams; D, copper nail or pin; E, putty; F, screw pin; G, nut of same.

CHRYSANTHEMUMS FLOWERING IN APRIL.

THE conservatory and greenhouse without Chrysanthemums during the dark months of early winter would be void of the great charm of the season, but it is rarely that we find them decorating the greenhouse within such a short time of Easter. We have two plants now in flower of Fair Maid of Guernsey, and it affords me great pleasure to forward a flower of each plant.

The plants are from cuttings taken in January, 1883. They were placed in 6-inch pots during March, and kept in a cool frame until the usual time of potting. Finding, however, we had more than we required for pot culture, the plants now in flower were planted out in spring on a border with an east aspect. There they remained all through the summer months. They were stopped twice while on the border, and were taken up and potted about the middle of September. This gave them a severe check, but after standing a few weeks under a north wall they eventually recovered, and left outside as long as safe from frost, being taken into a cool house towards the end of October.

They were kept back as much as possible, and were not taken into the greenhouse until after Christmas. Flowers were produced in the beginning of January. These being constantly cut a second growth was made, upon which they are now principally flowering, and I do not hesitate in saying they will continue flowering up to Easter.—J. S. B.

[The flowers received are as pure and fresh as we usually see them in November and December.]

ROYAL HORTICULTURAL SOCIETY.

APRIL 8TH.

VARIED and interesting in a more than usual degree was the Kensington meeting of Tuesday last, Daffodils being still in the ascendant; but in addition there were rich stores of Azaleas, new and beautiful, Rhododendrons in abundance, Orchids and miscellaneous plants being similarly numerous.

FRUIT COMMITTEE.—Harry J. Veitch, Esq., in the chair. Present, Messrs. John Lee, G. Goldsmith, S. Lyon, J. Willard, G. T. Miles, W. Denning, R. D. Blackmore, and G. Bunyard. The exhibits before this Committee were comparatively few. A bronze Banksian medal was awarded to Messrs. T. Rivers & Son, Sawbridgeworth, for a collection of sixty dishes of well-

kept Apples, all being remarkably fresh and sound. Very fine were Blenheim Pippin, Seek-no-Further, Peck's Pleasant, Gloria Mundi, Beauty of Kent, Dumelow's Seedling, Melon Apple, Newtown Pippin, Baldwin, Annie Elizabeth, King of Tomkin's County, and Mère de Ménage. Mr. Goldsmith, Hollenden, Tonbridge, had seven dishes of Apples; Winter Queening, Northern Greening, and Court Pendu Plat being fresh and sound. Mr. G. Fennell, The Gardens, Fairlawn Park, Tonbridge, sent a dish of Brabant Bellefleur, which were commended for their freshness. Mr. Witney, Brayfield House, Newport Pagnel, Bucks, showed good examples of the dwarf early Cabbage All the Year Round with white solid hearts. He also sent samples of a neat Seakale named The Pearl. From the Royal Horticultural Society's Gardens a large collection of Rhubarb was sent, similar to that described at a previous meeting.

A first-class certificate was awarded to Messrs. Veitch & Son for—

Ellam's Dwarf Early Spring Cabbage.—An excellent early variety, with a close solid head, somewhat sugarloaf-like in shape.

FLORAL COMMITTEE.—Section A.—Rev. G. Henslow in the chair. Present, Messrs. T. Moore, J. Laing, F. R. Kinghorn, J. Woodbridge, H. Herbst, James Hudson, H. Williams, H. Ballantine, J. Dornay, J. O'Brien, and E. Hill. Section B.—Shirley Hibberd, Esq., in the chair. Present, Messrs. H. Bennett, W. Bealby, G. F. Wilson, J. James, G. Duffield, J. Douglas, H. Cannell, and W. B. Kellock. Messrs. J. Veitch & Sons, Chelsea, contributed a group of superb Amaryllises, several of which were certificated, but amongst those that were not so honoured were the following:—Warrior, brilliant scarlet, white central stripe, four flowers in a head; Adelina Patti, white, streaked with rich rose crimson, neat flower, four in a head, very beautiful; Gustave Doré, intensely dark scarlet, three flowers in a head; Washington, bright light scarlet, white central stripe, four flowers in a head; Lothair, dark scarlet, the colour running down to the centre. The collection was shown chiefly to show the diversity of colouring that is being obtained in this class of plants, and it is rather strange that the Committee declined to certificate one of the most distinct yet raised—namely, Adelina Patti, described above. A choice collection of new plants was also contributed, comprising the neat white-flowered *Dendrobium barbatulum*, *Dendrobium Devonianum album*, white, blotched with yellow; *Cælogyne ocellata*, white, with an orange lip; *Cypripedium microchilum*, the white-flowered hybrid between *C. niveum* and *C. Druryi*; *Lælia flava*, with neat yellow flowers; and *Cypripedium venustum*, a hybrid between *C. argus* and *C. villosum*, with flowers much resembling the latter parent. A profusely flowered plant of *Azalea indica Caldwelli ignea*, which has neat reddish hose-in-hose flowers, was very attractive, and the mauve-purple *Azalea ledifolia* fl. pl. from Japan was noteworthy.

Mr. B. S. Williams, Upper Holloway, contributed several Amaryllises and Azaleas, amongst the latter being some striking varieties—Madame Estelle Cavelier, rich deep red; *Bignoniæflora*, rose, double, free; *B. punctulata flore-pleno*, small, white streaked with rose and red, full and free. Henrich Heine, rich, almost violet purple, double, and extremely profuse, were some of the best. A good *Cattleya Mendelli gigantea* was noteworthy, and a small plant of *Angraecum dependens* with pure white flowers and long spurs. Messrs. Barr & Son, King Street, Covent Garden, were awarded a bronze Banksian medal for a pretty group of Daffodils, arranged in a similar style to the collection at the Crystal Palace Show—namely, in bottles concealed by moss. There were fine masses of *incomparabilis plenus*, *concolor expansus*, *lorifolius Emperor*, *albidus Leedsii*, *Burbidgei grandiflorus*, and *bicolor maximus*. Several new varieties were also staged and certificated. Mr. Woodbridge, The Gardens, Syon House, Brentford, sent three or four scapes of *Hymenocallis macrostephana* with from six to nine flowers each, large, pure white, and exquisitely fragrant. A cultural commendation and vote of thanks were accorded to Mr. H. Bennett, Shepperton, Middlesex, for a dozen blooms of Her Majesty Rose, in grand condition, very substantial, excellent in form, of good size (some being $4\frac{1}{2}$ inches across), and of a most lovely delicate rose tint. Most of the blooms were shown at the Crystal Palace on the preceding Saturday have evidently lasted well. Mr. T. Sibbald, Bishop Auckland, sent a pan of *Herniaria glabra* and *aurea*, the ordinary dark green and golden forms.

M. Louis Van Houtte, Royal Nursery, Ghent, Belgium, exhibited a choice group of new Azaleas, representing some richly coloured varieties, both single and double. Certificates were awarded for nine of them—a sufficient indication of their merit. Very seldom indeed is an exhibitor so fortunate. Of other varieties not certificated the following were noteworthy:—Mrs. B. S. Williams, double white with a few pink spots; Sir C. Spencer Wells, single, intensely deep red; T. W. Moore, double, dark red, free; and John Hawkesworth, double, salmon red, very large and bold. Mr. R. Dean, Raneleigh Road, Ealing, contributed a choice collection of hardy flowers, for which a vote of thanks was awarded. They included some good examples of Bedford Yellow Wallflower, *Myosotis dissitiflora* Perfection, double *Anemone coronaria*, and *Primula White Queen*. A vote of thanks was accorded to Mr. Herbst, Richmond, for a collection of *Narcissus poeticus reflexus*, fresh and bright. Mr. C. Turner, Slough, had a box of Auriculas raised by Mr. J. Douglas. Several were certificated and of others the following were good:—Miss Taplin, Alpine, shaded violet purple; Seepre, Alpine, dark shaded crimson; and Cecilia, rich shaded crimson, Alpine. A vote of thanks was accorded to Sir Trevor Lawrence, Bart., M.P., Burford Lodge, Dorking, for a handsome plant of *Cypripedium levigatum*, with three spikes of three flowers each. Sir Charles Strickland, Bart., Hildenley, Malton, Yorkshire, was accorded a vote of thanks for two plants of *Cattleya citrina*, each bearing a fine flower. A cultural commendation was awarded to Mr. S. Cook, gardener to D. B. Crawshaw, Esq., Rosefield, Sevenoaks, for a plant of *Dendrobium Cambridgeanum*, with three growths bearing from five to eight flowers.

A silver-gilt Knightian medal was awarded to Messrs. H. Lane & Son, Great Berkhamstead, for a fine group of Azaleas and Rhododendrons, which unfortunately, owing to the limited space, were somewhat crowded. The Rhododendrons were remarkable for their dwarf compact habit and large dense heads of variously coloured flowers. A bronze Banksian medal was awarded to Messrs. J. & J. Hayes, Lower Edmonton, for groups of decorative Pelargoniums and the Fairy Rose longifolia, which has bright crimson double flowers produced in great abundance. A silver Banksian medal was awarded to Messrs. Cutbush & Son, Highgate, for a fine group of greenhouse plants. *Eriostemons*, *Darwinias*, Azaleas, Heaths, and similar plants were particularly well shown. A silver-gilt Banksian medal was

awarded to Mr. T. S. Ware, Tottenham, for a large group of choice hardy flowers, Primulas, Anemones, Daffodils and Muscaris. Especially notable were some pans of the bright blue *Anemone appennina* and its white variety. Messrs. Shuttleworth, Carder & Co, 191, Park Road, Clapham, exhibited a pan of *Masdevallia Shuttleworthii* bearing some dozens of flowers, also a fine *Odontoglossum Wilckeanum*.

First-class certificates were awarded for the following plants:—

Odontoglossum crispum guttatum (Sir Trevor Lawrence).—Flower very neatly formed but rather small, white ground heavily spotted with dark brown.

Oncidium cucullatum giganteum (Sir Trevor Lawrence).—A beautiful variety with unusually large flowers, the sepals and the petals very dark, and the lip a uniform mauve purple tint, and a few darker spots near the base.

Cypripedium ciliolare (Sir Trevor Lawrence).—Somewhat suggestive of *C. superbiens*, the dorsal sepal broad, veined with green and tinged with purple, the petals edged with dark hairs, suffused with purple, and spotted with a much richer shade of the same colour. The lip is neatly formed and dark purple.

Odontoglossum Shuttleworthii (Shuttleworth, Carder & Co.).—A very distinct form of the *O. Alexandræ* type, with a lip like *O. Wilckeanum*, the sepals covered with brown to near the tips, the petals broad and heavily spotted with the same colour.

Phaius irroratus purpureus (Veitch).—A hybrid between *Phaius grandifolius* and *Calanthe vestita*, very interesting and pretty. The sepals and petals are narrow, white, somewhat like the *Calanthe* parent, the lip like the *Phaius*, of a rosy crimson colour.

Amaryllis Virgo (Veitch).—Flower of moderate size, scarlet with a white centre bar in each petal. Four flowers in a head.

Amaryllis Zitella (Veitch).—A most distinct and beautiful variety, the flowers rather rough but distinct in colour, white ground streaked and flushed with a distinct and pretty shade of rose.

Davallia Mariesi cristata (Veitch).—An elegant form of this well-known Fern, the fronds of which terminate in a neat bunched crest.

Adiantum strictum (Williams).—Previously described.

Narcissus bicolor J. B. M. Camm (Barr).—Very neat and softly coloured, petals creamy white, and crown $1\frac{1}{2}$ inch long, pale lemon yellow, margin slightly revolute.

Narcissus incomparabilis sulphureus Queen Sophia of the Netherlands (Barr).—A handsome variety, remarkable for an excessively long name, and beautiful form. Flower 3 inches in diameter, petals broadly elliptical, pale yellow. Crown shallow and saucer-like, $1\frac{1}{4}$ inch across, rich orange with a wavy margin.

Narcissus incomparabilis James Dickson (J. Dickson & Son).—A magnificent variety with flowers 4 inches in diameter, the petals $1\frac{1}{4}$ inch broad, elliptical, pale yellow. The crown is $1\frac{1}{4}$ inch deep and as much in diameter, pale orange, the margin waved.

Narcissus Leedsii Queen of England (Barr).—A beautiful variety, flowers $3\frac{1}{2}$ inches in diameter; petals white, elliptical; crown pale clear yellow, three-quarter inch deep, and 1 inch across, with a slightly recurved margin.

Auriculas Mungo, St. George, and Conservative (Turner).—Previously certificated.

Azalea Princess of Wales (W. Nicholl, Lower Merton).—Pure white, full flowers, the margin of the petals slightly undulated.

Azalea Souvenir du Prince Henri (Van Houtte).—Double, rosy crimson, very handsome, full, the petals much waved. Very free, and of good habit.

Azalea Souvenir du Duc d'Albany (Van Houtte).—Single, a magnificent variety, the flowers pure white 5 inches in diameter, the petals broad and undulated on the margin. The finest white variety yet obtained.

Azalea Mlle. Marie Stockman (Van Houtte).—Double, pure white, almost like a *Petunia*, very full, substantial, and handsome.

Azalea Baron Nathaniel de Rothschild (Van Houtte).—Double, violet purple, very distinct in colour, extremely free and beautiful.

Azalea Mr. B. S. Williams (Van Houtte).—Single, flowers very large, 4 inches in diameter; the petals rounded, of a rich rosy crimson colour.

Azalea John T. D. Llewelyn (Van Houtte).—Double, very handsome variety, broad rounded petals, white faintly suffused with pink, with spots at the base of deep rose.

Azalea Comte de la Torre (Van Houtte).—Single, well-formed flower, white suffused with pink, the upper petals heavily spotted with red.

Azalea Comte de Paris (Van Houtte).—Single, broad rounded flower, pink, the petals edged with a broad white band.

Azalea Comte Andrien de Germiny (Van Houtte).—Single, of a peculiar reddish colour, the upper petals purple.

SCIENTIFIC COMMITTEE.—Dr. M. T. Masters in the chair.

Canker in Apple Trees.—A communication was read from Mr. Plowright on a form of this disease as caused by *Nectria ditissima*. He observed that Sphaeriacei usually attack dead organisms, but there are some exceptions, as *Valsa parvularia* on living Oak, and many of the *Dothidiaceæ*. The specimens sent were from several localities, but in almost every case the cankered part bore the fungus, and which was not found anywhere else. He likewise forwarded drawings illustrative of the growth of the fungus. When the parasite gains an entry into the bark of a medium-sized branch it at first causes the death of the bark and subjacent wood to only a limited extent. The bark cracks concentrically. In the cracks and upon their edges the perithecia are most commonly found. They are most abundant in those cases in which the devitalised area has become surrounded by an enlarged and swollen margin of healthy bark. Further details will be given when the paper and figures are published in *extenso* in the *Gardeners' Chronicle*.

Cecidium Fabæ.—Mr. Plowright also sent specimens of Bean plants with this fungus artificially produced. They were infected with the germinating teleutospores of the *Uromyces* on the 6th February; on the 29th the spermatogonia began to appear. It was not until the end of March that the perfect *Cecidium* was developed.

Apples Diseased by Fungi.—Mr. Murray and Mr. Smith reported that the Apples brought to the last meeting by Mr. MacLachlan were attacked by *Septorium Ralfsii*.

Potato Culture to Prevent Disease.—A plan of the cultivation carried on under the direction of the Sub-Committee appointed at the last meeting was shown, while Mr. Murray informed the Committee that every Potato

had been carefully examined, and about twelve rejected that were found to be diseased.

Gymnosporangium Juniperi.—Mr. A. Smee exhibited branches of Juniper badly diseased. It was suggested that experiments should be carried out to impregnate the Hawthorn and *vice versa*. He also brought some malformed *Calceolarias*, which were referred to Rev. G. Henslow for examination and report.

Primulas.—Col. Clarke exhibited the results of crossing the true florists' *Polyanthus* crossed by the garden Primrose. This cross, recrossed by the former, gave innumerable varieties of colour in the seedlings. He observed that he had often tried to cross the Cowslip with the Primrose, but had always failed.

Agricultural Implements from Naagar Hills, Assam.—Dr. M. T. Masters exhibited a number of rude implements used by the natives, who were almost unknown to Europeans, consisting of a hand-plough, a large round-ended knife, used also for village fights, and wooden hoes, together with samples of the native produce—*e.g.*, Chick Pea, Rice, &c.

LECTURE.—The Rev. G. Henslow first called attention to a group of Australian plants exhibited by Mr. Cutbush, containing species of *Correa* known as native Fuchsias, as they somewhat resemble that plant, but belong to a very different family; the leaves of some species are used as tea. Species of *Boronia* and of *Leptospermum*, the latter of the Myrtle family, and therefore allied to the Gum Trees. *L. lanigerum* grows to 30 feet, and furnishes wood for the spears of the natives, while *L. scoparium* supplies the hard and heavy wood called Manauka wood in New Zealand. *Genetyllis*, called *Hedaroma* by Lindley, and also *Darwinia*, is remarkable for the mimicry in its flowers; for while the latter are minute and inconspicuous they are surrounded by coloured bracts in the shape of a Tulip. A species of *Epacris* furnished a comparison with *Erica* or *Heath* to illustrate their "representative" character. Though apparently resembling one another, yet their floral structure is different; and while *Erica* is found at the Cape, *Epacris* characterises New Holland. The lecturer remarked on two characteristic features of the foliage of Australia—its harshness in some, and the habit of hanging vertically in other plants, so that the latter affords little or no shade. The dryness of the atmosphere is accountable for the harshness, and the object gained by those plants with vertical foliage is probably the same as that acquired by the so-called "sleep,"—namely, to avoid the ill effects of radiation at night. This is seen in species of *Acacia*, which generally in Australia have no blades but only a flattened leafstalk or phyllode, the edges of which point sky and earthwards. He next called attention to a remarkable "bigener" of Mr. Veitch—*viz.*, a cross between two genera, *Phajus grandifolius* and *Calanthe vestita*. The latter Orchid (*"Botanical Magazine,"* 4671), discovered by Dr. Wallich in India, and flowered at Messrs. Veitch's establishment first in 1848. *Phajus grandifolius* (*"Flore des Serres,"* &c., vii., p. 259), is from China, with yellow orange sepals and petals, the labellum alone being purple. In the bigener the flower is white, as in *Calanthe*, but the labellum of a rose colour. *Angræcum dependens*, exhibited by Mr. Veitch, is remarkable like other species of this genus for the long spur; that of *A. sesquipedale* is usually over 1 foot long. Tropical Africa and Madagascar supply them, and it is remarkable that it cannot be fertilised except by some insect with a proboscis as long as the spur. One species, *A. fragrans*, furnishes a material for a tea in its leaves, which are used in Bourbon, Mauritius, and in Paris for pulmonary complaints.

A species of *Acacia* with spinescent stipules called for remarks on the peculiar modifications which those organs undergo, and the lecturer described the remarkable "Bullock's-horn" Thorn, as *A. sphærocephala* is called, of Nicaragua, and the peculiar habit of ants which live in them, and are supplied with food by the shrub in the form of honey in honey pits on the petiole, and oily "fruit bodies" at the apices of the leaflets. These ants keep others off which would strip the tree of its foliage.

Plumbago and *Statice* furnished remarks on the peculiar method of securing fertilisation secured by the former genus, both being of the same family. The ovule is suspended by a curved funiculus, and the tissue of the style is prolonged downwards till it reaches the micropyle, thus conveying the pollen tubes directly into the latter. Many species are excessively acrid in this juice, such as *P. scandens*, called *Herb du Diable* of San Domingo. Beggars use the juice for raising blisters, as they do in England with the juice of *Ranunculus scellaratus*. He next called attention to a hybrid raised by Mr. Veitch between *Cypripedium niveum* and *C. Druryi*, in which the yellow colour of the latter had disappeared but the narrow lip retained, the flower of the hybrid being white.

AZALEAS AT SHIRECLIFFE HALL.

THE Azalea house at Shirecliffe Hall, Sheffield, the residence of H. E. Watson, Esq., J.P., is now quite ablaze with a rich profusion of fine blossoms of varied colours and markings. Every year at this season the house is noted for a good display, but probably on no previous occasion have the plants been so laden with flowers as at the present time. They are all of a bushy character, and have been grown from small nursery plants, but have not yet attained a large size, the largest specimens in the collection being $4\frac{1}{2}$ feet through. Some, of course, are more floriferous than others, but the majority are masses of rich colours, quite dazzling, and many have their foliage completely hidden by the thickly clustered blossoms. All are very healthy and vigorous, and show unmistakably that unremitting attention has been given to their requirements. Shirecliffe unfortunately is situated too near the manufacturing portion of the town, and the large volumes of noxious gases emitted daily from the numerous furnaces and huge chimneys which are dispersed thickly over that suburb, with the assistance of the fumes of a neighbouring gasworks, are destroying all vegetation except the most robust and hardy kinds. The beautiful Oaks that for years were such an ornament to Shirecliffe and surrounding district are fast dying in consequence of the poisonous state of the atmosphere. Those at Shirecliffe are nearly all dead. The successful cultivation of many plants under glass is therefore conducted at a great disadvantage, but the health and beauty of these Azaleas prove that they are plants adapted for town life.

The old variety *A. indica alba* still finds favour here, and for delicacy and purity of colour it is not excelled by any other variety in the collection. Three or four plants, about 4½ feet in height and breadth, are well flowered, and though the individual blooms are smaller and the petals narrower than most newer varieties, they are light, elegant, and more beautiful than many larger-flowering varieties. Another white variety—*Mdlle. Maria Lefebvre*—is just opening its blossoms, and those fully expanded are about 4½ inches in diameter, pure white, and of good substance. This is a splendid variety and presents a striking contrast to the one just mentioned. *Reine Cleopatra* is all aglow with an abundance of rich magenta-coloured flowers, and is very beautiful. *Superba*, a small plant, about 3 feet through, is so thickly covered with fine flowers that they have not sufficient space to expand properly, and this occurs in other specimens. *Stella*, *Jean Vervaenc*, *Lizzie Tillery*, *Cedo Nulli*, *Countess of Beaufort*, *Gloire de Belgique*, *Dr. Moore* (a most charming variety), and *Roi Leopold* are each covered with well-shaped flowers of good substance and colours. *König Wilhelm* is covered with rich deep rose blossoms very double, and associated with the single varieties is very striking and beautiful. *Apollo* is one of the most showy and effective white varieties grown here; two or three specimens are notable for the size and substance of their numerous flowers. Other varieties in this house of equal merit are *George Loddiges*, *Mdme. Louis Van Houtte*, *Bernard Andreas alba*, *Countess of Flanders*, *grandis*, and *Charmer*. I also noticed a small plant of the *Amœna* type (*Princess Maude*) covered with blooms that afforded a good contrast with the large-flowering varieties. A plant of the new variety *Flambeau* is just opening its buds, but its chief recommendation appears to be its rich deep colour, and in this respect I do not think it has an equal, but the flowers are inferior both in size and width of the petals. It is to be hoped, however, that it will ultimately become, through the skill of the hybridiser, the parent of a variety possessing the richness of its colour with superior blooms. Disbudding *Azaleas* is recommended by some authorities, but it is not practised here, every bud being allowed to remain, and with good results.

At one end of the house there are two fine Orange trees growing luxuriantly in tubs 2 feet square, laden with large numbers of fine expanded flowers and opening buds, that fill the house with rich fragrance. Looking up the middle of the stage over the gorgeous masses of rich colours these trees form an appropriate background. They produced good crops of excellent fruit last year, and promise an abundant one this season. All flowers are enhanced in value and more attractive if richly perfumed, and as the *Azaleas* are devoid of this quality, where Orange trees are not grown a few pots of *Mignonette* placed amongst them when in blossom would render the houses in which they are grown both fragrant and pleasant. A batch of fine *Cyclamen* up one side of the house are just going out of flower after a long season of beauty. The seeds were sown on the 3rd of March, 1883, and have produced fine healthy corms. This season's blooming commenced in the early part of last November, and continued for a period of nearly five months, many of the plants having borne 300 fine flowers each, and for a considerable time about fifty have been opened at a time. The other side of the house is partly occupied by a batch of *Strawberries* in pots that are in good health and promise to yield a crop of luscious fruits that will outrival even the Orange blossom with their delicious and tempting fragrance.

The whole is highly creditable to the head gardener, Mr. J. Udale, and is a proof of his ability and skill; his success may in part be accounted for by the fact that he never appears to be satisfied to rest on his oars and glide with the stream, but is anxious each year to produce better results than he accomplished the previous season. "I hope to do better next year" seems to be his motto, and it might be taken up by others with advantage to all.—J. H. S.

RHODODENDRON VEITCHIANUM.

I ENCLOSE for your opinion a single bloom of a seedling *Rhododendron*, raised from *R. Veitchianum*. There were four in the truss. I have raised several seedlings from *R. Veitchianum*, and though none excels the parent, they will be very useful varieties. I have had a pyramid plant of *R. Veitchianum* in flower for two months, bearing nearly two blooms, and the trusses very large, many having four blooms each. Cuttings of this fine plant have struck very readily with me, and are making vigorous growth, small roots from the main stem being the best, and it saves the flowering wood of the plants.—G. R.

[The flower received was quite flaccid. Though not superior to the parent, it is evidently a pretty variety worthy of preservation.]

KITCHEN GARDEN.

WORK in the vegetable garden must not be neglected this month, as on timely attention to it depends in a great measure the success of the year's vegetable supply. Sowing and planting must be the

order of the day. Wet weather may hinder this, but nothing else should be allowed to do so.

Asparagus.—Reading Giant and Connover's Colossal are splendid varieties, and all who wish to raise young plants of them should sow the seed now. Any light rich soil will suit them. Sow the seed in rows 1 foot apart. Open the drills 2 inches deep and fill with old potting or sandy soil. We sow 2 ozs. of seed annually at this time, and have hundreds of roots from it which come in to make good the plantations broken into every winter for forcing. Many heads from the old roots are now showing through the ground, and quantities will be ready for cutting by Easter. It is when at this stage of growth we have seen it much benefited by stimulants, and we always give them now. We mix salt and guano in equal parts, and shake a small handful over each crown when it is raining. This is soon washed down to the roots and does much good. It is applied fortnightly until the plants are fully in growth, or indeed until cutting is discontinued.

Beetroot.—A short row or two of this may be sown at once to supply early roots. The Egyptian Turnip-rooted is the earliest of all.

Parsley.—Where there is no sign of plants from the seed sown in February sow again in another situation. A supply of this is absolutely necessary, and failure must be guarded against.

Kidney Beans.—A few of these may now be sown on a south border. They must have a free and open soil and a sunny situation. They are the most tender crop in the garden in spring, and they must be treated as such. Our first sowing is generally made at the base of a wall, and they answer well there. We have lately found Cooling's Ne Plus Ultra to be one of the earliest dwarf Beans. The drills for the reception of the seed should not be more than 3 inches deep, and the covering should be light and friable.

Broccoli.—Sutton's Late Queen is again coming in with us in fine condition. Broccoli in general should now be sown. All are put in at the same time. Some think that autumn varieties should be sown earlier than those which do not become useful until the spring, but it is not so; the variety and not the time of sowing produces a succession. Veitch's Self-protecting Autumn is the best of all for use from the end of October until the new year. Then comes Backhouse's, Cooling's Matchless, Carter's Spring, and Sutton's Queen. These are our main varieties. A good patch of seed of each should be sown, either in rows or broadcast, as they will only remain in the seed ground until they are large enough to transplant.

Savoy.—Sow a quantity of the Green Globe variety.

Kale.—This should also be sown, and so should the main crop of Brussels Sprouts.

Carrots.—The main crop should be sown as soon as possible. Ground which was heavily manured last year will be most suitable for them. A dressing of soot, salt, or lime forked in now will benefit them more than anything, and assist greatly in keeping away grubs. James's Scarlet Intermediate is the most useful for a main crop. Sow in drills 2 inches deep and 15 inches apart. Cover and roll down firmly.

Cauliflower.—All early plants in frames should now be planted out. Nothing but rich ground will produce fine heads. Planting between Pea rows is an excellent plan to secure shelter for early plants. Those which do not grow much, but "button" prematurely, should be drawn up at once, and fill their places with others. Sow successional crops. Webb's Mammoth and Veitch's Autumn Giant, if sown now, will give a supply from August until the Broccoli is ready.

Potatoes.—Take the lights off frames on fine days. Cover at night when frost appears. Early-planted ones in the open are now pushing through the soil. Frost would ruin them, but protection must still be seen to. By drawing the soil well up to and over them they may be kept from harm for a long time. Where this cannot be done use Spruce or Laurel branches to protect them from frost and cutting winds. Finish planting late crops.

Celery.—Transplant seedlings into boxes or beds where they can have a gentle heat. If placed 3 inches apart they will grow into bushy plants previous to being transferred to the trenches. Turnip-rooted Celery comes quicker to maturity than the tall sorts, and it is equally good for stewing or flavouring.

Clip Box edgings. Hoe down and remove all weeds from paths and vegetable quarters, and have everything in the vegetable garden neat and attractive.

FRUIT-FORCING.

FIGS.—*Early Trees in Pots*.—The fruit of the early varieties, such as Early Prolific and Early Violet, will soon show signs of ripening, when the supply of water must be gradually reduced, and syringing in their case must cease; but Brown Turkey, Negro Largo, and White Marseilles will need a little more time, and to these give liquid manure twice a week and syringe once or twice a day. Ventilate freely, but avoid currents of cold air, for much as the admission of air improves the texture of the foliage and the quality of the fruit, cold draughts cripple the foliage and are highly injurious. When the days are bright and the wind cold it is advisable to turn off the heat early in the morning, so as to allow the pipes to get cool and lessen the necessity for much ventilation, turning on the heat again at closing time. The night temperature should now be kept at 60° to 65°, 65° to 70° by day from fire heat, and keep between 75° and 80° through the day with sun heat. Close early and allow a rise of 10° after closing, as Figs to swell off well need abundance of heat and full exposure to the light. Surface-dress the soil with decayed manure.

Young Plants in Pots.—Trees potted last month should be shifted into 10-inch pots before they become rootbound, using plenty of crocks and a compost of chopped turf, a sixth of old decayed manure, and a tenth of

old mortar rubbish. Keep the plants warm; indeed, if intended for early work, they must be grown in an early house and near the glass, where they will make a free early growth, and become thoroughly ripe before autumn. Pinch out the points of the shoots to increase the number of breaks.

Succession Trees Planted Out.—Look well after the trees in stopping the side shoots at the fifth or sixth leaf, and the terminals where space is limited. Thin the side and other shoots to prevent overcrowding, it being essential that the growths have full exposure to light, and tie and regulate the shoots so as to secure a proper supply of bearing wood throughout the trees. Mulch the borders with short manure, and give tepid water copiously, keeping the mulching moist. Syringe twice a day in fine weather, and between 2 and 3 P.M. close the house on fine afternoons.

PEACHES AND NECTARINES.—Earliest Forced House.—Maintain a steady night temperature of 60° to 65°, with a rise of 10° to 15° by day from sun heat, until the stoning is completed, which is now nearly effected. When this is effected, and ripe fruit is wanted as soon as possible, the temperature may be kept at 70° to 75° by day from fire heat, and 10° more from sun heat, closing at 80°, with plenty of moisture in the house. This will swell off the fruit to a good size. It is not advisable, however, to increase the night temperature, as it tends to an ill condition of the wood, the fruit being finer and the young wood of better quality when the ripening is accelerated in the daytime only, taking advantage of fine days to close early. Syringe twice a day until the fruit gives indications of ripening, when, the syringing ceasing, a good moisture should be secured for the benefit of the foliage by keeping the surface of the borders damped morning and afternoon. Remove all surplus fruits directly the stoning is over, and any fruit not well placed for colouring should be turned to the light and supported by thin laths placed across the wires of the trellis. Tying down the shoots will need attention, judiciously stopping gross shoots or terminals when they have made moderate growth; remove superfluous growths, and keep laterals closely pinched to one joint. Water inside borders freely with tepid liquid manure, and mulch with short manure to attract and keep the roots at the surface. Ventilate cautiously in cold weather, as the tender growths are soon injured by cold currents.

Succession Houses.—Tie in the growths as they advance; disbud and otherwise thin the shoots, so that no more growths will be retained than are necessary for furnishing the trees and for next year's fruiting, having them sufficiently thin that the foliage will be fully exposed to light and air. Thinning the fruit must also have attention. When it is swelling freely the number may, when the trees are in good health, be safely reduced to that required for the crop, as to allow twice as many to swell and stone as will be considered essential for the crop is to lessen the size considerably of those that are allowed to ripen. Syringe freely twice a day in fine weather, and always sufficiently early to allow of the foliage becoming dry before night, using clear rain water, as some spring waters leave a sediment upon the fruit and spoil its appearance. Fumigate upon the first appearance of aphides, choosing a calm evening, and being careful to have the foliage dry. Keep a sharp look-out for red spider, especially on the trees over the hot-water pipes; and if forcible syringings do not overcome the pests an insecticide must be applied promptly, as under no circumstances must it be allowed to become established.

Late Houses.—The trees have set the fruit well, and thinning will be needed as soon as the fruit is fairly on the swell, doing it gradually, removing the smallest and worst-placed. Disbudding likewise must be proceeded with gradually and frequently. Admit air fully day and night in mild weather so as to keep the fruit back, it being in a forward state and likely to come in before the succession houses are over. Syringe in the afternoon early enough to have the foliage dry before night, and in the case of unheated houses close moderately early in the afternoon when there is a prospect of frost.

PLANT HOUSES.

Begonias.—These are amongst the most useful and beautiful of plants for the winter, and shoots for cuttings are now plentiful of such kinds as Ingrami, Knowsleyana, and other good varieties that flower freely. Cuttings should be inserted in pots or pans in sandy soil, and if placed upon a shelf in a warm house they will root quickly. It is a mistake to place them in close moist frames or under bellglasses, for they are very liable to damp, which is not the case when stood upon shelves and shaded from the sun. The last-named comes true from seed, and a stock of plants can be readily raised, which if confined at the roots for some time before they are required in bloom, will flower as profusely as those from cuttings.

Begonias manicata and *heracleifolia* are two of the most serviceable we possess for the conservatory where a night temperature of 45° to 50° is maintained. They will stand in this condition for two months or more, provided they are placed in just before their flowers expand. When arranged amongst other flowering plants they give to the whole a light and elegant appearance. The last-named is the more showy of the two, its flowers being larger and deep pink. It should be grown in larger numbers than *B. manicata*, but this variety cannot be dispensed with. Young stock is the best for winter, unless large plants are required, and the plants should be annually raised by cuttings. These are taken off and placed singly in 3-inch pots in a compost of loam, leaf mould, a seventh of manure and sand, a little of the latter being placed in the centre of each pot for the base of the cutting to rest upon. These strike as readily as the other varieties on a shelf, or stood in a warm house, if kept shaded from the sun.

Centropogon Lucianus.—Cuttings will now be plentiful and should be rooted and grown for next winter flowering, for there is no better

or more useful plant in cultivation. During that season its bright scarlet flowers, which are produced in succession, are very effective in a stove, intermediate, or conservatory temperature. In the two cooler houses the flowers last the longest and are of a brighter colour than when in strong heat. The growths are produced along the sides of the old flowering shoots should be slipped off with a small heel and inserted in sandy soil in 5 or 6-inch pots. They are longer rooting than some plants, but will root freely either in the propagating frame or in a warm house; if kept shaded by the former method they root the quickest. After a sufficient stock of young plants has been raised do not throw away the old stock, but cut them close down, and when they start growth from the base turn them out of their pots, reduce the old ball by about half, and then repot them in the same size. Use for a compost good loam, a little manure, and sand.

Linum trigynum.—This is generally placed amongst greenhouse plants, but those who subject it to greenhouse treatment will not achieve success. It enjoys heat during the spring and autumn, while during the summer months it will do well under cool frame treatment. It is best raised by cuttings annually for winter flowering, as the old plants are never so satisfactory as those that are grown freely and quickly. The young tender growths are the best for cuttings, and will form roots in about ten days in brisk moist heat. They root so quickly and certainly that it is advisable to insert them singly in small pots, as when rooted they can be grown without receiving any check, which they receive when divided and potted. As soon as they are well rooted the points of the young plants must be pinched out to cause them to branch. Stopping the shoots must be particularly attended to as soon as a little growth has been made, so that bushy little specimens can be produced by the time they can be placed in cold frames.

Plumbago rosea.—Old plants that flowered during the winter and have been reserved for stock will now have abundance of strong cuttings. It is important to have good cuttings to start with; if obtained early they are but little better than flower stems, and sooner than employ these for cuttings it is wise to postpone their insertion for a week or two. They root readily, and as soon as sufficient cuttings have been taken the old stock may be thrown out. Insert the cuttings singly in small pots the same as the *Linum*, and in a short time, in brisk heat, they will form roots, especially if under a bellglass or in the propagating frame. The variety known as *ecceinea* is very bright in colour, but grows taller, consequently both should be grown.

Sericocephalis Ghiesbreghtiana.—Another useful old plant for the winter, and, when well grown, it is invaluable for cutting and conservatory decoration. The tops of the shoots should be used for cuttings, and inserted singly in small pots, as they will root freely under the same conditions as those mentioned above.

THE BEE-KEEPER.

SPRING FEEDING.

At the present time and for some weeks to come bee-keepers will be occupied chiefly in feeding-up their stocks, so as to have them as forward as possible when honey is abundant. Comparatively few, however, understand the true principles of spring feeding, or "stimulating" as it is more properly called, and we think a few notes may not be unacceptable to our readers, especially the inexperienced ones, which will enable them to work less by rule of thumb and more in the light of knowledge as to why certain operations are undertaken at this season. If bees are safe as regards risk of perishing from actual want of food, they should be undisturbed until the first or second week in March. We speak of the northern counties, in the south a week or so earlier. This advice may appear somewhat late, but instructions have already been given in your columns for feeding; and our object now is to explain more fully the principles involved.

The first fine day will see the bees carrying in large quantities of pollen. This income after the long repose of the winter months causes considerable excitement as well as activity among them, and excitement from any cause is invariably followed by a rapid rise in the temperature of the hive. The natural result of this is a thorough warming of the cluster. The bees spread themselves out, giving the queen more freedom to move about on the combs; and she will, if this increased warmth is maintained for a day or two, commence ovipositing much more freely than before. On the other hand, if a day's busy pollen-gathering is succeeded by cold weather, the excitement subsides, the bees cool down as it were, and cluster as closely as before. If the bee-keeper selects the right day when the bees are thoroughly roused, and supplements the pollen obtainable by a continuous supply of thin syrup, he has it in his power to keep up the abnormal warmth of the day's busy work, and the bees are stimulated or forced just as plants are by the action of a hotbed. To make the matter quite clear, it must be understood that the bees' share of the work is simply to create and maintain a temperature sufficiently high to hatch the brood, while a good queen is always ready to produce as many eggs as the bees can attend to.

When a start is decided on warm the food slightly. Do not give the first bottle till the evening, because a rapid supply of syrup given to half a dozen stocks on a warm day would be almost certain to induce a tendency to rob all round, and this should be very carefully guarded against. The following morning remove the bottle, whether the food is all taken or not, and substitute the slow feeder. Another thing must not be overlooked. Any weak stocks must be left unfed till all the others are well accustomed to the feeding-bottle. If a weak stock is fed at the same time as strong ones, probably it will be attacked and the food taken from it as rapidly as given, in which case it is almost impossible to preserve it. The feeder should also be carefully guarded against bees reaching it from the outside.

About half a pint of syrup should be given as rapidly as the bees will take it on commencing to stimulate, after which we think the best guide as to quantity is one pint (or $1\frac{1}{2}$ lb.), given at such a rate as will occupy seven days in taking the whole. Three and a half ounces per diem may not seem a great quantity to maintain a large colony of bees, but it must be remembered that by the time the stocks become strong there will be a natural income in addition from Gooseberries, &c., so one pint is abundant food for a week. If there is much sealed food in the hive a comb may have the cappings removed, and if placed in the centre of the bees they will at once take the honey to another part of the hive, leaving the cells ready for eggs.

When stimulating is successfully started the increased warmth of the coverings about the feeder becomes very perceptible. The bees constantly crowd round the source of supply, and are always on the look out for the food. The entrance to the hive must be contracted to about 1 inch, and every means be taken to add to the warmth of the coverings. There is no need for ventilation after February is passed, and crown boards may be used with advantage over the quilts.

There is always a difficulty in improvising an efficient feeder. High-priced ones are only used by the few, but a very effective article may be made at a nominal cost and with little trouble as follows:—Take a common pickle-bottle holding about a pint, cut a square of very thin zinc (the thinner the better), mark on this a circle the size of the bottle mouth, and with scissors cut the zinc so that the parts projecting beyond the circle may be bent down the neck of the bottle and tied on with string. Three small holes punched in the zinc will give about the right quantity of food. If a thin board the same size as the top of the hive has a $1\frac{1}{2}$ inch hole cut in its centre, is laid over the quilts with a half brick or other weight on each corner to keep it down, a capital feeding stage is formed, and it only needs a small piece of glass for slipping over the hole when removing the bottle to make it complete.—W. B. C., *Higher Bebington*.

LIGURIAN AND SYRIAN BEES.

THE debate originated by "W. B. C." and carried on by others on the inferiority of the Ligurian bee as a honey-gatherer appears to be of national interest to English bee-keepers and of serious moment to all. If the Ligurians are unsuited to the English climate—for, as I understand it, "W. B. C." does not dispute their value in countries where the honey flow is lengthy—by all means let us face the truth, or in a few years' time we shall repent the obstinacy in acknowledging an error which many of us do not like to own. On the other hand, if those who find Ligurians profitable will give accurate details of the manner in which they have proved themselves ahead of blacks, we shall have done something towards arriving at the truth.

The recent contributions on the point are against the Ligurians, but "Hallamshire" brings a new element into the argument by his advocacy of the importation of the Syrian bee. When looked at with an unbiassed eye I fear his warm commendation of them will not hold good. "W. B. C." has not tried them, others have. The "American Bee Journal" has a very clear and—being from the pen of Mr. Doolittle—I may add faithful article on the subject. It is on page 132 of the present volume, but being three columns in length I can only quote small portions of it. "I had one colony of Syrian bees during 1883, and three till after the honey harvest of 1883 with their increase, and from all I did not get 50 lbs. of honey, and I had to feed each to get them prepared for winter. The same number of Italian colonies gave me 500 lbs. during the same time." So much for yield. Mr. Doolittle then goes on to speak of the propensity these bees have for keeping fertile workers, "that the apiarist would suppose they had a laying queen, and is deceived until the chance of getting the colony into condition is passed."

Then as to stinging. "The 10th of December being warm, I took out two frames to feed them. As Mr. Carrol wrote me that I would have less difficulty in handling the Cyprians if I used no smoke, I placed the smoker, well filled and lighted, on top of next hive. I had not got the quilt half off before two dozen bees darted at me. . . . I allowed two or three to sting my hands while I watched them. Some of them would bite half a dozen times before they would sting." Then smoke was tried till it rolled out of the entrance; "it helped some, but still I got twenty-five stings"—which is not a pleasant picture, I think "Hallamshire" will admit. If Syrians in the hands of such an able bee-master

as Mr. Doolittle are unmanageable and profitless, surely it is fair to suppose the generality of English bee-keepers will be better without them. But to refer to "Hallamshire's" own letter. Would he give particulars of the case that he can cite, in which £20 profit was made in one year from one stock? Was it in comb or extracted honey? How much from the parent stock, and how much from the swarms?

I have some recollection of a statement of the sort in print; but as I believe the bulk of the profit was derived from the sale of swarms or queens, and was, if I remember rightly, in 1881, when all stocks—black or yellow—gathered enough to winter upon, I presume "Hallamshire" refers to some other colony, for profit derived from the sale of swarms does not touch the question, except in an adverse way. Moreover, such isolated instances give a fictitious colouring to the craft which is hardly advisable.

To hark back to the original point. By all means let bee-keepers thankfully and industriously use the columns of the *Journal of Horticulture* to sift this question thoroughly, giving the Ligurian due justice where facts bear out theory; but carefully weighing his gilded and specious appearance and amiable manners against the more sober and, I venture to think, more substantial qualities of the hitherto abused black.—K. B. K.

At page 253 "Hallamshire" speaks of the Syrian bees having realised all his wishes, and cites a case where £20 profit has been made in one season in this country from one stock, another where the increase was £7, and each gathered sufficient to winter on, while twenty black stocks failed to swarm, and had to be fed to winter. Was the above profit made from honey alone, or by rearing queens and selling them at high prices? and were the blacks and Syrians treated alike? If by uniting the two extremes a Syrian queen mated with a black drone is so successful as honey-gatherers, may not the same be said if a Ligurian queen was mated with a black drone? More particulars are required on this subject, as few bee-keepers would object to investing 22s. in a queen if there were a prospect of realising £20 profit in one season. "Hallamshire" has now a good opportunity of bringing the merits of the Syrians before the public by competing in the "Blythe competition," the object of which is "to show the relative merits of different systems of bee-keeping, and to prove to the cottager that bee-keeping, if conducted on economical principles, is highly remunerative to bee-keepers." Any bees are eligible.—A. TYKE.

TRADE CATALOGUES RECEIVED.

* * All correspondence should be directed either to "THE EDITOR" or to "THE PUBLISHER." Letters addressed to Dr. Hogg or members of the staff often remain unopened unavoidably. We request that no one will write privately to any of our correspondents, as doing so subjects them to unjustifiable trouble and expense.

Correspondents should not mix up on the same sheet questions relating to Gardening and those on Bee subjects, and should never send more than two or three questions at once. All articles intended for insertion should be written on one side of the paper only. We cannot reply to questions through the post, and we do not undertake to return rejected communications.

Label in Glass Tube (G. Ashforth).—No doubt the label was good when you sent it off, but it was useless on arrival here, as the glass tube was smashed to atoms. The method of enclosing paper labels in glass tubes is not new, Mr. Cannell of Swanley among others having them in use.

Pear Blossom on Young Wood (P. G.).—Although not frequently seen because of overcrowding of the growths in summer and close pruning in winter, it is yet not by any means an uncommon occurrence for blossom buds to form on wood of the previous season's growth. We have gathered some of the finest of Pears that were produced in the manner indicated.

Magnolia conspicua (Aurora).—This is no doubt the name of the Magnolia to which you refer. It has flowered freely in March near London this year, and the trees were and are yet strikingly and conspicuously beautiful, and all the more effective when seen against a background of evergreens, and in the twilight. Light yet rather firm soil is the best adapted for this Magnolia, and a sunny position, as under those conditions it grows sturdily, and the wood ripens well. In rich soil or damp positions the growth is often too succulent and immature for yielding a profusion of handsome and delicately fragrant blooms. We never feel it a trouble to answer inquiries that may benefit our readers.

Lettuce (*E. T. H.*).—Probably you are right, but we cannot speak positively on the matter.

Name of Beetle (*W. H.*).—The insect forwarded is one of the predacious water beetles (*Dytiscus marginalis*). Although aquatic in habit, they will sometimes quit ponds and ditches to hunt land insects, and should they occur in a garden they would be rather beneficial than otherwise.

Non-Execution of Order (*J. R.*).—There is evidently some mistake somewhere; the advertisement does not appear very explicit. We will write to the advertiser on the subject. Possibly, however, by this time you may have heard from him yourself.

Sowing Seeds (*Orchid*).—It is absurd to suppose that there is any advantage in sowing seeds on any particular day in the calendar; on the contrary, great disadvantage may result if the weather and ground be unfit for the reception of the seed on the stipulated days. Your neighbour must be very credulous to believe such nonsense as is published in his almanack. The Orchid you have sent is *Tricopilia suavis*.

Garbled Citations (*Exit Verity*).—The note you have sent, if printed, would be enigmatical to the majority of our readers. When a person resorts to altering another person's language, and founds thereon an argument, he ceases to be a fair controversialist, and damages his own reputation in the most effectual manner.

Bulbs Decayed (*G. Long*).—Your garden appears to be infested with a species of *Julus*. Does the land need draining? Soot and lime liberally dug in would be useful, and in addition to that we should place wood ashes round the bulbs when planting. Are you sure the bulbs were sound when planted? and were they planted in good time? Watering the beds with a mixture of petroleum and water (2 ozs. of the former to a gallon of the latter) would probably be advantageous. Try it now and note its effects.

Planting Standard Roses (*S. B.*).—It is late now for planting Roses; still they will grow if the roots are kept quite moist when out of the ground, not otherwise, and the stems and branches also kept as moist as possible. At the time of taking up the Roses we should shorten every shoot closely, leaving only about two dormant buds on each. Should the weather prove dry after planting haybands wrapped round the stems and kept moist would be very beneficial, and if made and applied neatly would not have an unsightly appearance. The Shallot to which you refer is probably the Large Brown Russian.

Preparing and Spawning Mushroom Bed (*S. W., Scarborough*).—It is just possible you kept the manure too long under preparation in the shed, but still the bed will probably gather heat. Cover it thickly with straw, and if this fails remove the top 6 inches of the bed and place in a layer of warm manure, replacing the former. A newly made bed often remains apparently cold for a few days, then the heat rises more or less rapidly. It should rise as high as it will, and then when declining insert the spawn; if inserted when the heat is rising the mass may become too hot. A thermometer plunged an inch or two in the bed is a safe guide, as when it registers 80° the bed will be right for spawning. Failing an instrument, let a stick be kept in the bed, and when it is new-milk warm the manure will be suitable for the reception of spawn.

Aerial Roots on Vines (*W. C. B.*).—The presence of roots in large numbers issuing from the stems of Vines suggest that the roots in the borders are not affording the requisite supply of nourishment for supporting the growths and foliage, or that the atmosphere of the house is kept unduly moist. These adventitious roots cannot be regarded as "beneficial," neither is their removal beneficial nor apparently injurious. When they occur no harm is done by leaving them to shrivel, and, except that their appearance is objectionable, they are not usually removed in a fresh growing state. The address of the Secretary of the Leeds Gardeners' Benefit Society is Mr. W. Sunley, Bacchus Hill, Moor Allerton, Leeds.

Good Semi-double Zonal Pelargoniums (*C. M.*).—Amongst so many that are good it is somewhat difficult to select a few of the best. The following are chosen from one of the best private collections (Mr. McIntosh's at Duneevan) as likely to meet your requirements:—Guillon Mangilli, purple-pink with scarlet; Monsieur Buchler, dark purple; Madame Thibaut, pink; Lucie Lemoine, flesh; Atala and Commander-in-Chief, orange-scarlet; David Thomson, dark crimson; Ferdinand de Lesseps, scarlet, light eye; Metis, crimson, white eye; Orestis, shaded magenta; Ellen and Imogen, salmon; Sybil Holden and Lady Sheffield, shaded pink and purple; Mrs. Leavers, bright rose; Lucy Bosworth, light rose; Eureka and Prima Donna, white. West Brighton Gem, a variety of Wonderful with cream-coloured flower stems, you might also find useful.

Roses not Expanding (*C. W. D.*).—Your plants are evidently unhealthy, but the cause of their present unsatisfactory state we have no means of determining in the absence of any particulars as to the treatment the plants have received. Perhaps the soil is sour by overwatering, or on the other hand it may have become too dry at some time, causing the roots to shrivel; at any rate it is almost certain the root-action is defective, as if this were not so, and sufficient water was given, there would have been no occasion for shading the house during the late bright weather. Have you employed too much fire heat and kept the house too close? You say you have good "fire-heated flow and return hot-water pipes," but do not say a word as to the temperature you have maintained, nor your method of ventilating. Employ as little fire heat as possible to keep the temperature from falling below 45° at night, and open the ventilators half an hour after the sun shines on the house in the morning. Perhaps your plants need fresh soil; if so repot them, using a compost of good loam and a sixth part of old manure with a little gritty matter for keeping the soil porous, and encourage them to make good growth in the open air in summer.

French Beans Failing (*Bean*).—You have stated quite sufficient to enable us to account for the flowers dropping off the plants. You will neither be able to grow Beans nor anything else satisfactorily where the flues are so defective as to admit such a volume of smoke and noxious gas into the house. It appears to us that an otherwise good structure is rendered useless by a defective flue. Such a house is well worthy of being heated by

hot water; but if this method is denied you must have a flue without a fissure anywhere for the exit of smoke, or you will not succeed in growing anything when fire heat is employed. Well-constructed flues of good sanitary pipes, but not in immediate contact with the furnace, where fire bricks should be used, have been found satisfactory in many places, and cheaper than brick flues. A good flue is useful, a bad one worse than nothing, for it is a destructive nuisance.

Azaleas and Heaths Unhealthy (*An Amateur*).—Azaleas well managed flower profusely every year. They require to be firmly potted in good peat soil with a little leaf mould and sand intermixed and very carefully watered, neglect or mistakes in this respect quite nullifying everything else that may be done for them. If once the soil gets quite dry the hair-like roots shrivel, the leaves fall from the plants, and flowers consequently cannot be produced. A greenhouse temperature suffices, a little extra heat in the spring when growth commences, and copious syringing being advantageous. Plants that are very unhealthy are difficult to restore. Close pruning will not benefit them, but removing a good portion of the old soil and repotting in fresh of the nature indicated, using pots as small as possible, and pressing the soil very firmly, always keeping it moist but never saturated, placing the plants in a warm greenhouse or vinery, syringing them at the least twice a day, may possibly induce them to commence fresh growth. That is the only way in which they can be improved. Heaths in a "mangy" state are perhaps still more difficult to renovate. They must not be pruned below the foliage or they will die, and the general treatment as advised for Azaleas may be adopted, except that they will be better in a cool frame than a warm house. Only experienced amateurs and good cultivators can grow these plants satisfactorily. More extended notes on culture will shortly be published in this Journal.

Vine Eyes not Growing (*F. C.*).—We are glad to hear from you again, and particularly regret to learn of your protracted indisposition. It is just possible that however attentive your "help" may have been, that if you could have attended to the Vine eyes yourself you would have had similar success as on a previous occasion, provided—and this is important—that the eyes were cut from hard, well-ripened, and nearly pithless wood. We quite understand the condition of the incipient plants now, and do not despair that some of them at least will grow freely if the wood was of the nature indicated. It is very common for Vine eyes to elongate for an inch or two and then cease growing. The first spurt is supported by the food that was stored in the wood round each eye, and when this is exhausted before roots are formed the growth must perforce cease until they are produced. In the meantime it is better not to disturb the eyes at all, or root-formation may be arrested. Possibly the atmosphere of the house may be rather dry; if so, place a handlight or bellglass over the Vine eyes. The frame in which you raised Vines before would contain more moisture than the house.

Pines not Fruiting (*Idem*).—The plants are not too old to fruit. It is not too late for them to throw up and ripen their fruit this year, and you may grow Pines in a house with the temperature named if you manage them properly. Unless your plants are of extraordinary size the pots are too large, and in all probability the plants have had too much water in winter. In such pots, plunged, and in the low temperature of 56° to 60°, water would not be needed at all during the months of November, December, and January, then about one watering in February and two in March would suffice. Let the soil get dry now until the leaves lose their crispness, and also let the temperature remain as it is. This will give the plants a check, and in the course of a month you will have no difficulty in maintaining a night temperature of 70°, and this may induce the plants to show fruit. The previous check they received would not prevent their fruiting now, unless it prevented their attaining a fruiting size. We suspect they have too much root space, and have been kept too moist during the winter.

Names of Fruits (*C. B.*).—We have carefully examined the Apples, but quite fail to identify the varieties. They are possibly local, and have not had other than local names. Please send the Peas as soon as possible; half a pint will be ample.

Names of Plants (*H. M.*).—The plant of which you send flowers is *Sparmannia africana*, which succeeds well in greenhouses, attaining a good size. There is no difficulty in obtaining it from nurserymen who grow collections of greenhouse plants for sale. (*Honeysuckle*).—*Lonicera sempervirens*. (*L. W.*).—*Magnolia conspicua*. (*Begonia*).—It is almost impossible to expect anyone to name plants from specimens crushed in an envelope and macerated by the stamping of the post office. Judging from the fragments, No 1 is perhaps *Begonia Ingrami*; 2, *Alonsoa Warscewiczii*; 3, *Violet Devonensis*. (*F. A. M., Sevenoaks*).—We do not undertake to name varieties of Coleuses; no one can do so accurately from solitary leaves, especially when they are imperfect examples. (*Climber*).—The spray is quite insufficient for identification, and, besides, it was quite shrivelled on arrival. (*W. E. B.*).—1, *Eranthis hyemalis*; 4, *Spiraea Thunbergii*. The blue flower is *Muscari botryoides*, and the white one *Iberis sempervirens*; from those the numbers were displaced. (*H. H. G.*).—1, *Begonia argyrostigma*; 2, *Weigela hortensis nivea*; 3, *Narcissus incomparabilis*; 4, *Chrysanthemum segetum*; 5, *Adiantum macrophyllum*; 6, *Asparagus plumosus*. Not knowing the treatment the Fern has received we have no means of determining the cause of its sickly appearance. (*M. C. B.*).—The large white flower is *Magnolia conspicua*, the other is *Tecoma capensis*.

Bees (*T. Marriott*).—Your hive is doubtless a strong one, and evidently does not need to be fed. We would not advise you to put on supers before the end of this month or the beginning of May, and only then if the season is favourable. The stock hive ought first to be filled before you put on the supers. The size of the supers is a question of taste.

A Weak Hive (*W. C.*).—It is difficult to advise as to the best course to be pursued without some knowledge of the stock of bees in question. If they are reduced to "only about a handful" through some inherent defect of the queen you had better destroy them and close up the hive, or the probability is the bees of your strong stock will plunder it before the present month is out. The combs and food being "clean and healthy" will give a

capital start to a swarm from your strong hive, especially to a second swarm. On the other hand, if the stock is one which swarmed late last year the young queen may have had no chance of developing her laying powers. In this case you could give her the needful help by transposing the stocks on a fine day when honey is coming in freely, not otherwise, or the strange bees might encase the queen and probably destroy her. Bear in mind that you will throw your prosperous hive considerably back by robbing it of the greater portion of its adult population, and nothing but anxiety to save a young and fertile queen will justify the experiment. You must contract the entrance and wrap all up as warm as possible for fear of chilling the brood. On the face of your communication, and from the fact that you are "only a learner," we rather deprecate the idea of your trying to save the few bees and queen left in the weak stock. It will be the wiser and safer course to let well alone, and not run the risk of further "unsatisfactory experiments." Operations which could be successfully accomplished by an experienced apiarian often fail in the hands of a novice.

COVENT GARDEN MARKET.—APRIL 9TH.

ALL branches of the trade dull, with good supplies, Strawberries especially meeting with little demand. Prices without alteration.

not be discouraged, but proceed, assisted by our long experience, in adapting rotations to soil, climate, and other circumstances. In doing this we cannot consent to give up sowing Wheat after Clover, because it does not necessarily follow that if the mildew in Wheat prevails to a greater extent than after any other preparation it is in consequence of the Clover plants and roots being ploughed in; but we think it is from various other causes, such as late sowing, late ploughing, and also the application of farmyard manure, which it is the general custom to lay on the Clover lea. Early ploughing, especially in the second growth of Clover, gives the land time to settle, and it really requires no manure in that case. If, however, any is given, let it be bone superphosphate or bone meal drilled with the seed, as all nitrogenous manures tend to produce an excessive bulk of straw. Late ploughing and late sowing often cause deficient plants in various ways, the attack by slugs or wireworms, and the later gathering and more tillering required is therefore sure to render the Wheat straw more liable to suffer from the mildew, as they are comparatively immature and irregular at the time of ripening, and in consequence of the comparative absence of silica in the straw of all those crops which have made an unusual effort to reach the period of harvest. We have noticed on various farms, and especially on the chalk hill farms, where large flocks of sheep are usually maintained, that instead of ploughing the Clover leas early and allowing them to become settled and stale on the surface and sowing the seed early, we find great objections to early sowing are taken, in consequence of the flock requiring all the Clover feeding possible and thus delaying the seed time, which, fifty years ago, was at least six or eight weeks earlier than under the present system. Late sowing also frequently sacrifices a large portion of Wheat, through the plants being lifted by late frosts in the spring, especially when the seed is drilled and buried shallow, whereas, if sown after the presser, the plant has a deep root-holding of the soil which bids defiance to spring frosts.

Taking all the facts into consideration we assert that it is not the Clover lea which is at fault, but the management and preparation generally speaking. Yet it is well to remember that the germs of the mildew fungus is alive, or may be in all farmyard manure, and that in case of using farmyard manure it should be applied on the young Clover plants in winter or early spring, thus manuring the Wheat crop indirectly, and at the same time adding greatly to the crop of Clover, and especially of the roots, which are, according to Dr. Voelcker's analysis, so valuable as a manure for the succeeding Wheat crop. It is, however, difficult to farm without Clover lain preceding the Wheat upon dry and friable land, but on heavy land, being part of a farm, the Wheat crop, when the land is free from couch, may follow a lain of half Clover and half Beans; but on a well-tilled land in a high state the Wheat would be succeeded by Lent corn, which in case of the Wheat having suffered from mildew, the Lent corn also may suffer in the same way.

It is the revival of the mildew spores which we should dread the most when the manure made from mildewed straw was applied to a cereal crop, therefore it is best to grow roots or green crops, Beans or Peas, after the Wheat instead of before, and apply the yard dung to them, because these crops are not subject to mildew like the cereals, as Beans and Peas are only blighted by the black or green aphides. Beans and Wheat from time immemorial have been the rotation in various districts of strong rich land, particularly upon a chalk subsoil, and the Wheat crop seldom becomes mildewed. Again, in our own case, we had certain fields which grew fine crops of Wheat and Potatoes alternately for many years. These crops of Wheat never suffered from mildew, although we had serious injury done to a late-sown crop of Wheat when substituted for Lent corn. The sowing of certain sorts of Wheat in districts subject to mildew is also of importance, because the white Wheats are more delicate in growth and suffer more than the red Wheats, which are of a more robust habit of growth.

With regard to the influence of certain manures, it has come out in evidence, received from Mr. Little's correspondents, that nitrate of soda and also farmyard manure having been applied for Wheat, that those crops suffered more than when some other dressings were applied, such as nitrogenous and ammoniacal manures, woollen rags, soot, rape cake, decorticated cotton cake, heavy folding of sheep, excessive manuring, and liquid manures. Dr. Voelcker's letter to Mr. Little upon the subject is important as well as interesting, which for want of space we can only give in a short or condensed form. Speaking of the analysis of a soil he gives a reply to his correspondent who seeks information, who had for seven years successively suffered from mildew in his

MILDEW IN WHEAT CROPS.

(Continued from page 276.)

In continuation of this subject we must endeavour to show how lands can be cropped in succession to avoid the ill consequences which the scientific men of the day assure us must inevitably accrue to a cereal crop if the manure made from mildewed straw is applied to land under cereal crops. As nearly all our farm crops have enemies and diseases peculiar to them, the cereals are all liable to mildew, and the mildew not being confined to Wheat alone, but also to Rye Grass, &c., renders the choice or selection of crops necessary in a rotation to avoid mildew; and it restricts our selection very much, especially as the cereals are, after all, the real paying crops of the farm, and although frequently sold at a low price, as for some years past, yet with ordinary care in choosing our customers there is a ready sale and the money sure.

Let us see how the four-course rotation will assist us in evading the effects of mildew. It is stated by various correspondents who replied to the questions issued to the practical farmers by Mr. Little, that Wheat after Clover seeds and lea has suffered far beyond any other preparation, for twenty-one correspondents give evidence as to the injury after Clover, but only six returns show the disease as occurring after Grass seeds and ordinary Grass leas. This is extremely disappointing to many, for their preconceived opinions, based upon science and practice, have for a long period given Wheat out of lea or Clover the preference to any other preparation when adopted in the rotation. This being proved renders our task more difficult in any attempt to alter the rotation; but we must

Wheat crops. He says, "I give you an abstract of my report:— 'Your soil is unusually rich in nitrogenous and organic matters, and it also contains more potash than most clay soils, which accounts fully for the fact that your Wheat and Beans got blighted, and made lots of straw and haulm in wet and cold seasons like those we have had for the last six or seven years. On the other hand, your soil is very deficient in phosphoric acid, and not over-rich in lime.' " This is only a small quotation from the report by Dr. Voelcker. It is, however, sufficient for our purpose of giving opinions obtained from our own practice. In all good land, but especially in those strong soils rich in potash and lime, sulphuric acid, &c., being deficient, nitrogenous manures should be avoided, but taking care that carbonate of lime obtained by chalk, or lime in its pure state, should be considered as manures more essential than many others for producing healthy plant growth. The best strong soils, when clean and free from couch, really require little or no ordinary manures, except mineral manures, such as bone superphosphate, or pure bone meal drilled with the seed, for then the sulphuric acid required and silica also will be available as food for the Wheat plant, and give a more healthy growth, enabling it to withstand with more or less success the influence of adverse seasons, and reduce the probability of injury from the attack of mildew and its germs or spores, which may prevail, no matter from what cause or source. In a letter from Sir J. B. Lawes to Mr. Little he enforces a previous opinion, by giving some particulars of plots of land which had grown Wheat only for a long series of years, and which had been "well and judiciously manured," and states distinctly that the remarkable variations in the proportion of offal corn, which his figures show "cannot be accidental," and he adds; "we know that in bad seasons the best crops are attacked with mildew, if that be the prevailing disease."

The conclusion we arrive at from the perusal and study of both Sir J. B. Lawes' and Dr. Voelcker's letters to Mr. Little is that the greatest produce of straw in the Wheat crop subjects it to the attacks of mildew; but the use of mineral manures to a great extent diminishes the injury by producing stiffer straw and less foliage, for gross foliage is always attractive to the germs or spores of the mildew fungus. We also from these facts arrive at the conclusion that we are also well repaid for our endeavours to avoid mildew even in fine seasons, for the effect of mineral manures generally gives a large crop of grain, and it being of greater weight per bushel gives it a full value in the market. We therefore give it as our opinion that the land cannot be successfully cultivated for the production of cereals on any soil where lime, or the carbonate of lime—chalk, is more or less absent.

WORK ON THE HOME FARM.

Horse Labour.—After nearly three weeks good dry March weather the rain, which commenced to-day while we write, March 31st, will, if not too continuous or persistent, assist the horses by accelerating the working of the land into a fine seed bed for Barley; for upon some of the strong soils the land has turned with a rather tough and cold furrow, but has dried so quickly as to become hard and difficult to reduce into a sufficiently fine tilth as a preparation for various seedings, such as Barley, Oats, and Mangold. In fact there will be now more than ever quantities of land laid into permanent pasture under the influence of a wide-spread and popular opinion that the cereals will not pay for cultivating or producing under present prices of grain. In consequence we must ask the home farmer to be sure and reduce the land to a fine tilth under any circumstances, for whether the grass seeds are sown on the Barley, Oat, or Wheat crop, or in case of the grass being sown on a fallow without taking a corn crop, still in every case the land should be firm and very fine, otherwise much seed will be thrown away by not vegetating at the proper time. The preparation will still be going on for Oats and Barley seeding, and should be reduced to a fine state, and thus not trusting the weather, which is a speculative transaction entirely on account of the uncertainty of the climate. A different idea as regards the seeding for the arable land prevails to a considerable extent, and the success so far of the ensilage question will begin to have an effect upon the minds of some farmers as to the policy of sowing with the Clovers the early and coarse sorts of the meadow grasses, and chosen with a double object in view—to be converted into hay as formerly, or ensilage under the new system, or fed by sheep and cattle as occasion may require. We have recently received so much information on the subject of making silos in the most economical manner, that it is being considered now whether any expense of consequence need be incurred where dry firm soils exist, especially those of chalk, sand, and limestone. In America a silo has frequently been improvised on almost any soil, and we are noticing almost daily that some farmers in this country, especially those who cannot afford an expensive silo, have turned out very useful ensilage from quite an ordinary pit under varying circumstances of soil and situation. On the chalk hill farms ensilage will be good food for in-lamb ewes as noticed in Mr. Wood's lecture the other day, and it proves better by far than trusting to roots and hay entirely to maintain them in good health and condition until lambing time. We are informed that the cheapest

silos have been formed by making a pit of the required size as to depth length, and width upon a chalk soil, which is sure to be dry, and will answer a temporary purpose without even cement, as applied to the sides, bottom, or ends, if covered with planks and loaded with dry earth has succeeded in preserving the ensilage in good form and condition. This may be done in any field where the materials are grown, whether it refers to Rye or Clovers, Sainfoin, or mixed grasses, yet in those cases where bullocks for fattening or dairy cows being fed at the stalls a silo of a permanent kind will answer the best purpose. Still, as we have so much yet to learn upon the subject, we shall defer any further remarks to a future time, as the question is really so extensive that events may easily occur to make it worth while for some farmers to wait until the present agitation has subsided on to something like a level basis, both as regards test of silo and other important matters in connection with the subject.

Hand Labour.—This is still very various, for the planting Potatoes, and manure carting, filling, and spreading, will require some hands where this work is still going on. Sowing the grass seeds by hand will be required where men are found equal to it, but the best sowers by hand are nearly all dead, and this work is now mostly done by Bennett's hand-barrow sowing machine, but even that requires more care in adjusting than is often taken to properly and evenly seed the land, for all light grass seeds should be sown separately from the heavy seeds like Clover, &c., because they will not run with regularity in the mixed state from Bennett's machine. Upon strong soils where the Oats or Barley is seeded to Clover, the water furrows should be carefully struck and made out, the earth from the spade should be widely spread, otherwise the small grass seeds will be too deeply buried.

Live Stock.—Easter being at hand, young lambs will be required, and are at this time selling well, quite irrespective of beef and mutton, and in the near future will be sure to sell well, because those in prime condition do not meet any foreign competition. With respect to the feeding of young lambs to be sold fat, this is a critical period, for any want of good and sufficient food being available, either for the lambs or their dams, it will reduce the condition of the lambs to a state from which they will not easily recover. The roots such as Turnips and Swedes, the latter in particular, will have lost much of their nutriment for stock-feeding unless they have been crowned down as we term it, for our practice formerly consisted in cutting off the greens and stems of them down to the crown of the bulb, and in this way they will remain sound in the land for months and prove good food for stock up to midsummer, for on various occasions we have been feeding the roots on the field where grown until midsummer in prime condition. This, however, was a plan we adopted before the Mangold crop became well known and available as food for sheep, because for many years it was repudiated as good for ewes and lambs. Those who have ensilage for feeding their fattening cattle, dairy cows, and farm horses, will now find it a good thing; but there are many circumstances which will require consideration as between it and Mangold, for even as food for farm horses both are very good indeed, and it enables them to perform more easily the work of the farm at the busiest period of the year, for when horses are kept on dry corn and hay only in the spring months, it is prejudicial to their health and power in work, even with an extra bait of corn, as compared with succulent roots or freshly preserved grass out of the silo. Dairy cows especially will frequently require abundance of succulent food or brewers' grains to enable them to maintain their best milk record.

REMARKS

30th.—Fair, generally dull, but a little sunshine; slight fog at night.
31st.—Dull, slight rain about 9.30 A.M.
1st.—Fine and warm, but with occasional sprinkles of rain.
2nd.—Very fine and warm; bright lightning in N.E. at 10.50 P.M. with rain.
3rd.—Loud thunder at 4.10 A.M. with short sharp shower; fine day.
4th.—Generally fair, with rain after 9 P.M.
5th.—A fair day, with occasional spots of rain; parts of afternoon and evening very fine and clear.
The early days of April have been very warm, with, as is frequently the case after such weather, rather sharp thunderstorms in the evening and night of the 2nd and early morning of 3rd. The former storms were several miles N.E. of this station; that in the early morning of the 3rd appeared to be in the N.W. of London, and to judge from the exceptional brilliancy of the flash and the long reverberations of the thunder the stroke must have been of exceptional violence, but as no structural damage has been reported it probably struck between two low-lying clouds.—G. J. SYMONS.

WINTER-FLOWERING ERICAS.

NO plants at the present time are grown on a larger scale for purposes of decoration than softwooded or winter-flowering Heaths; yet their cultivation appears to be limited to a few individuals, who grow them annually to perfection, and then they are disposed of for decoration all over the country. These model specimens find their way into the majority of gardens, and finally, I suppose, to the rubbish heap. This must be the case, for seldom indeed are they to be found in private establishments well grown; in fact, their successful cultivation does not appear to be generally understood.

The greatest hindrance to their cultivation is probably the mistaken notion that they will not do well a second year, and that they cannot be well grown in the provinces. There is no foundation for such ideas, if only skill, time, and labour can be accorded the plants, as can be fully demonstrated. There is another evil through which hundreds of these Heaths are annually injured or killed. This results from crowding them amongst other flowering plants in conservatories or other similar structures. Fire heat is generally used in these structures, and often the plants have to be stood upon open trellises directly over the pipes, which dries them too rapidly. In addition to this, they are often carelessly watered, being either too dry or too wet, which only adds to the evil, and this is not the condition of plants in solitary instances, but in many places.

I do not intend to detail any system of propagation, for there is neither time nor convenience in private gardens to attend to this, and it is not necessary, for good plants can be purchased cheaply. I shall rather endeavour to detail their cultivation from the time they are in 4 or 5-inch pots, which will be more useful at this season of the year. The time to purchase the plants entirely depends upon what they are required for. If to be grown into large specimens, they should be obtained any time from the present up to June; if for decoration, buy them in the autumn when set with buds, which is the best in the majority of cases.

To grow plants on into a large size it is best to start with those that have never flowered, but have been prepared for flowering next winter. These will be healthy little plants in 5-inch pots, and could after received be grown in cold frames. Their young shoots will be 2 or 3 inches in length, and should be allowed to extend until June without being stopped, when the points of all their leading growths should be pinched out and the strongest tied out, bringing them gradually towards the rim of the pots. If kept close for about a fortnight they will break into growth again and should be transferred into pots 2 inches larger. After potting they must be kept close until their roots are working freely in the new soil, when they can again be grown in a well-ventilated house, as in the earlier part of the season. These plants may be again pinched in September, but not later, so that they can pass the winter safely with sturdy growths about 1 inch in length. These will not flower under

this treatment, but will form grand bushes 7 or 8 inches through, and will be in the most satisfactory condition for flowering the following autumn if grown without stopping. If larger plants still are required, grow them the second year subject to the same treatment of stopping, and potting when needed; but one shift will probably be ample; though this depends upon the quantity of roots made in the 7-inch pots early the second season.

Old plants, or those obtained in autumn, need every attention while in flower as regards watering and position if they are retained for another year. After they have flowered in any structure where a little heat has been maintained, they should not be placed in a cold greenhouse, or they will be checked after being excited into action; but should have a temperature at first very similar to that in which they flowered, and should be carefully and gradually hardened to cool treatment again. They should be cut close back after flowering, and if kept in rather a close atmosphere at first they will soon break into growth. In fact, *E. hyemalis*, *E. Wilmoreana*, and *E. melanthera* are benefited by being kept rather close until they commence growth; but this must not be attempted with *E. gracilis* or *E. caffra*, or they will soon become a prey to mildew, for they cannot endure a confined atmosphere.

There can be no doubt that the best time to repot winter-flowering Heaths is directly their roots are active in spring. Cut-back plants, for instance, will be ready as soon as they have made from half to 1 inch of growth. The sooner potting can be done in the season the better, before the sun has too much power. The longer water can be withheld after potting the better for the plants, because it gives their roots ample time to recover. The old soil, before being turned out, should be moist, but not too wet. The soil for these plants should consist of firm fibry peat and a liberal dash of silver sand. The former must be good and of a nature that will not become sour through watering quickly, at the same time it must not be too light. After the plants are turned out of their pots remove carefully the drainage from the base of the old ball, but do not attempt to liberate the roots, for this is injurious and often proves fatal.

The pots in which the plants are to be placed must be well drained. A large crock should be placed at the bottom, over this a few smaller pieces carefully arranged, on these some still smaller, and over all some of the roughest of the compost. In potting the collar of the plant should not be buried, and sufficient space must be left to hold plenty of water to soak the whole mass of soil. The new soil must be made firm in the pots to prevent water passing through it and leaving the old soil dry. Large shifts should not be given, those in 5-inch pots being placed into 7-inch, while *E. gracilis* and its varieties should have the smallest possible shift, for they appear to flower more freely when their pots become full of roots by the time growth is completed.

After potting, if the plants have been subject to ordinary greenhouse treatment during the past few weeks, they may be placed in cold frames and stood upon ashes, or a similar moisture-holding material. The position of the frame must be such that the sun will not strike directly upon the plants, to render shading necessary; but if such a position cannot be found, moderate shade must be applied during bright sunshine, at least until they are rooting in the new soil. The frame should be kept close until they are in this condition, giving a little air only during the middle of the day when warm. Early in the afternoon damp the pots and material upon which the plants stand, and if very hot syringe the plants lightly and close the frame. This treatment will soon induce an active growth, when more liberal ventilation during the day and at night, also when mild, will ensure a strong sturdy growth. All through the summer too much air cannot be given. The lights should be drawn off the plants both day and night; in fact, they should only be employed to protect them from heavy rains. They will, when

in this stage, do well outside in a sheltered position. They might be plunged, but very careful attention is needed in watering. Where the rainfall is heavy it is not advisable to stand the plants outside, but the lights should be in readiness to place over them. This is of the greatest importance in autumn when their flower buds are formed, for if they become saturated they will often turn yellow instead of coming forward. It must be understood that *E. gracilis* must not be kept close for too long after potting.

When *E. hyemalis* and *E. Wilmoreana* are growing freely, and it can be seen which shoots are taking the lead, a system of thinning out the shoots may with advantage be practised. Plants that have been cut back two or three times are apt to make a large number of small growths, but if some of these are removed those left will be much stronger and finer, for it is wiser to have a few well-bloomed shoots than a greater number of smaller ones. It will be seen in autumn whether these Heaths are going to flower well or not, and if any plants have not been sufficiently ripened they should be cut back without further delay, and when housed should have the same treatment as those that have been stopped for growing into large plants. In winter they require a light airy position in the greenhouse. They must be carefully watered, and although they like abundance of air cold draughts should be avoided.

These plants require light shade from the direct rays of the sun for a time after potting and during the early part of the season. Whatever material is used for this purpose it must not exclude light, and should only be applied when very bright. Overshading is a great evil; the plants draw up weakly and will not flower satisfactorily—in fact, more Heaths are ruined through overshading than would be the case if none was employed. The plan is to select for them a position during the early part of the season where the sun will not strike with all its force upon them, and then shading material will not be needed. In such a position, when the lights can be drawn off the sun will not injure the plants, but the pots must be protected from its rays. When a number of plants are standing together it is generally the outer rows that suffer.

The secret of growing *Ericas* is in a judicious use of the water-pot, for if they are badly and carelessly watered, it does not matter how good the other treatment may be, success will not follow. More Heaths are killed through becoming dry than from overwatering. The general opinion is that they should not be watered before they are dry. That is a great mistake, for they ought never be in that condition. If they suffer from an insufficient supply of water their silk-like roots are at once destroyed and the foliage turns yellow, death eventually ensuing. When watered they should have sufficient to soak the whole soil thoroughly. If one application will not do this they must have two or three, as the case may be. They should then be allowed to stand until they require it again. But all the moisture must not be evaporated from the soil before water is applied; it should, when water is required, contain sufficient to keep the roots from suffering. It is difficult to explain minutely when water is needed, for this can only be gained by attention, observation, and experience.

Heaths may be encouraged by liquid manure when their pots are full of roots, but I am no advocate for supplying them through the spout of the water-pot. The only artificial manure I have tried for these plants is Standen's, and it is very suitable. The smallest quantity only should be sprinkled upon the surface. Three or four applications during the season will be ample. Plants potted in the spring will not need it more than once.

Mildew is the greatest enemy these plants have to contend against. It is easily destroyed by dusting the affected parts with flowers of sulphur. In applying it dew the plants with the syringe, and the dry sulphur will adhere to the foliage, or it may be mixed in water and the plants syringed with it. When applied be careful that the sulphur does not fall upon the soil and be washed down when watering the plants. The

same care must be exercised when washing it off the plants after the mildew has been destroyed.—WM. BARDNEY.

MOWING.

THE mowing machine is once again brought into action. On cold clay soils lawns that have been pretty well cut in the autumn do not make much progress before April, but in warmer soils it has scarcely ceased growing all this wonderfully mild winter, and is now becoming untidy. If it is too long for the machine it is much better to mow first with the scythe than to strain a machine in the endeavour to make it do work it was never intended to do. After the grass has been mown with the scythe and swept up it should be well rolled, and a few days afterwards the machine should be run over it in the usual way. If mowing with the scythe is not necessary let the lawns be well rolled a day or two before placing the machine upon them, and see that they are quite clear of stones, especially near walks where loose gravel is in use, as it is liable to be lifted with the foot or kicked on to the edges, and is very injurious to the machine.

It is a great mistake (one that is very frequently made) to set the machine to cut very close. The beauty of a lawn consists not so much in its shortness as in the evenness of the sward. When cut very closely it is much more liable to be burned in dry hot weather, there being nothing to protect the roots from the sun. The setting and keeping in working order is a matter that needs some little care, and as far as possible one man should always see to it. The first point is to adjust the knives to the sole-plate, so that it just touches, but they must not press against each other, or the mowing will be harder work, and there will be more wear on the machine than there need be. To regulate the height of the front rollers turn the machine on its side, place a straight-edge across the drum and front rollers, and measure the distance from the straight-edge to the sole-plate. The latter should stand about half an inch above the straight-edge. When the machine has front rollers it may be a little less, and when castors are substituted it may be a little more, as in wet weather the weight of the collecting-box makes the latter sink into the turf more than continuous rollers would do. Once or twice during the season the cylinder set screws will want turning a little closer, being careful to adjust both sides exactly alike. Other points in the management of a machine are to see that it is well oiled, and that the oil and grass are wiped off before it is put away after use.

It is not my intention to enlarge on the merits of the various machines, all of which, according to the various makers' ideas, are the best extant. There are not many gardeners who can boast of having had experience of all the machines in the market, and it is therefore the more difficult to decide which is the best. It is not so much a question as to which will give the greatest satisfaction when fresh from the maker as it is a matter of which will be found in the best condition at the end of three or four years. My opinion is that most if not all the machines now made are well suited to their work, and really more depends on the manner in which they are worked and kept in proper order than there is in selecting this or that maker in preference to others. Green's may be mentioned as a thoroughly tested type of our English lawn mowers, both as to their work and their durability. I have had experience of Green's for many years, and for an open level lawn I think it is excellent; but when mowing close up to overhanging edges of flower beds, or shrubberies, or on sloping banks it is not so suitable as some of those light handy machines of which the "Archimedean" was the forerunner. There is now a variety of these to choose from, all with their gearing neatly enclosed, preventing any chance of their getting entangled in any overhanging object, and they are equally adapted for working on sloping ground.

Large *versus* small machines is a question that has been previously discussed. Where there is a great extent of lawns comparatively open and but few trees and shrubs of course a horse or pony machine is preferable, if for no other reason than that it places the real hard labour on the shoulders of the horse instead of the man; but where lawns are crowded with specimen trees and shrubs it is very much better to have two or three small hand machines instead; and I also think that machines of 12 or 14 inches width are preferable to those of a larger size. Suppose, for instance, that a man and a lad work a 22 or 24-inch machine, and other two are working a 14-inch and a 12-inch, there is a gain in the space covered. Generally speaking I think it will be admitted by practical men that 20 inches is enough for a man and a lad to mow and collect the grass, while they will, with a light machine each, mow and collect 26 inches with little more exertion.

Another debatable question in connection with mowing is the collecting or non-collecting of the grass. Some have a great objection to leaving the grass on the lawn, and no doubt it is objectionable when the grass is allowed to grow too rank before mowing.

This, of course, is the fault of the workman, not of the system. Those who advocate having the grass uncollected also recommend more frequent mowing. As one who has practised this for some years I shall briefly state my reasons for doing so. In the first place the work is much lighter. Secondly, there is no stoppage to empty the grass-box, nor time lost in wheeling it away, consequently the work is much sooner done. Our mowing (without collecting) takes five hours' steady work, but when we put the grass-boxes on to the same two machines, with the same three men, it takes seven hours' hard work. Thirdly, the more frequent mowing keeps the grass in better condition. We mow every fifth day, consequently it is always in condition, and the little grass is scarcely ever noticed on the surface; but even this little scattered so frequently on the sward must benefit the lawn to some extent as a manure. Fourthly, although more frequently used there is really less wear on the machines, because there is never any strain put upon them, as is the case when mowing a very thick sward of some eight or ten days' growth. A day's work at this sort of mowing will sometimes do more harm to a machine than three or four days' light mowings. It is not necessary that only a certain make of machine be used for scattering the grass. I have long used Green's for this purpose, and though it certainly would be better if it was modified for the purpose of distributing the grass, still there is not much to complain of in this respect.

For mowing banks and round flower beds we use a small 14-inch "Coventry," and for this purpose it is admirably adapted. When mowing steep banks a rope is fixed to the centre of the machine, where the height of the handles is regulated. A lad by means of this rope keeps the machine from slipping down the bank, and at the same time assists to pull it along, while the man at the handles guides it. Where a rope cannot be used on account of shrubs or other obstacle on the top of the bank, the lad may hold it in position from the bottom by means of a stick with a hook in the end of it applied to the same part of the machine as the rope. It is a mistake to mow anywhere with a scythe when it can be done with a machine.

—A WORKING GARDENER.

ASPARAGUS PLUMOSUS.

Two more beautiful plants for the stove and warm fernery than *Asparagus plumosus* and *A. plumosus nanus* cannot well be imagined. They are quite distinct, so much so in fact that I consider no collection complete without plants of each of these elegant South African *Asparagus*. The older *A. plumosus* is climbing in habit, and is particularly well adapted for furnishing pillars as well as the lower portion of the rafter of the houses. At one time we grew it in the form of a bush, but found when the growths could encircle pillars or strong stakes they grew to a much greater length, and formed a greater number of elegant and beautifully green sprays. A pillar furnished with a strong plant covered with its diminutive white blossoms is pleasing to the most indifferent observers, while small plants in 4-inch pots are particularly pretty and serviceable for associating with flowering plants in the rooms of dwelling house and elsewhere. The sprays in a cut state are also much valued for using in bouquets and vases, as in addition to their lightness they are very durable, remaining fresh much longer than the fronds of any *Adiantum* with which I am acquainted. It can be rapidly increased, as the tiniest piece of spray when about three parts matured and older strikes like a weed, especially if placed in a moist heat and kept close either under bellglasses or a propagating frame. From one plant we quickly raised fifty, and the second season we could easily have struck five hundred if they had been required. I still consider it the better variety of the two.

A. plumosus nanus also grows most vigorously; and the peculiarly flattened formation of the growth which it invariably assumes at a proportionate height from the soil renders it very attractive and distinct. The fine foliage is more dense, which gives it a richer green shade than the climbing variety, but those constantly observing the two sorts tire soonest of the formal habit of the dwarf form. Unfortunately nothing will induce the spray of *A. plumosus nanus* to strike root; and as a careful division of the crowns is the only alternative propagation is both slow and risky. At any rate I advise those in charge of small plants not to be in a hurry to increase the stock, or they may find they are losing ground.

The cuttings in one case and the divisions in the other are best potted singly into small 60's, or if extra strong into any size into which they will fit readily, any light sandy soil suiting them. They must be kept in a moist heat, and shaded from bright sunshine till well established, and be gradually potted before they become much root-bound. Both varieties as they gain in strength will at regular intervals push up strong shoots, and if extra large plants are required they should be given liberal shifts and a rough rich compost. I find the best time to repot is when the last-formed growths are nearly matured, and also that they delight in a compost consisting of two

parts of roughly broken fibrous loam, one of turfy peat, with the addition of a little manure, charcoal, and silver sand. When well established the plants require abundance of moisture at the roots, and will be benefited by frequent supplies of liquid manure.

At the outset I was informed that the older variety would succeed in a greenhouse, but found they grew very indifferently in a cool airy house; in fact to have them in perfection they must be kept in a moist, warm, and shady position. Bright sunshine is ruinous to them, causing the eventual loss of the foliage, this being a check from which they do not quickly recover. The only insect pest to which they appear to be liable is mealy bug, but as these are very conspicuous no

Fig. 73.—*Narcissus incomparabilis* James Dickson.

difficulty is experienced in getting rid of them by hand-picking, provided they are not allowed to get thoroughly established. In this case the paraffin mixture would be necessary.—W. IGGULDEN.

NARCISSUS INCOMPARABILIS JAMES DICKSON.

THE Peerless Daffodil has yielded great numbers of handsome varieties, which have taken their place amongst the finest of the whole genus, and in popularity are inferior to none. A glance at one of the catalogues devoted to *Nareissi* or a visit to the London flower markets is sufficient to prove this. Of the few double Daffodils that are really appreciated, too, the forms of *N. incomparabilis* are pre-eminent, and with the double *Poet's Narciss* are most useful, the flowers lasting exceedingly well in rooms, and they have not that heavy and malformed appearance which is so noticeable in the *N. Pseudo-Narcissus* double varieties. There is, however, much less diversity in the double Peerless Daffodils than in the single forms; as in the latter there are not only

the ordinary deviations from the type, but by crossing with *N. poeticus* a series of distinct groups of hybrids have been produced, some of which combine in a remarkable manner the characters of both parents. Still, the whole of the *N. incomparabilis* family is very distinct, and Mr. Hibberd's idea of grouping these under the title *Chalice Daffodils* is not a bad one in a popular point of view.

Distinct in an unusual degree from the multitude of these *Chalice Daffodils* is the magnificent variety represented in fig. 73, and for which Messrs. James Dickson & Son, Chester, were awarded a first-class certificate at Kensington recently. So distinct, indeed, is it that some little difference of opinion was expressed amongst the *Narcissophiles* as to whether it was really a form of *N. incomparabilis* or not. The cup is so much larger and longer than is ordinarily seen in that species that the doubt lingering in some minds was excusable. Mr. F. W. Burbidge, however, gives the weight of his authority in favour of *N. incomparabilis*, and is, we understand, responsible for the varietal name bestowed upon it. There appears to be some evidence tending to show that the variety occurs in the north of England in a wild state, and it is said that flowers are frequently seen both in the Liverpool and London markets so that it must be abundant in certain districts if these statements be correct. It was sent to Dublin from Messrs. Dickson, and by them flowers were exhibited at Kensington. Perhaps some of our readers can add to this moderate history.

The flowers are of wonderful size, fully 4 inches in diameter across the petals. The latter exceed an inch in diameter, and are sometimes nearly $1\frac{1}{2}$ inch, elliptical in form, very thick and substantial, and of a pale but clear bright yellow. The crown or chalice is very handsomely proportioned, $1\frac{1}{4}$ or $1\frac{1}{2}$ inch in depth, and as much in diameter at the mouth, which has a slightly but regularly waved margin, and in colour is of a bright but not dark orange tint. The whole flower has a noble imposing appearance, which at once attracts attention.

PEAS IN POTS.

As a strong proof of the adaptability of the dwarf Pea known as *American Wonder* for early forcing, I may state that I have to-day (April 7th), gathered a good dish of Green Peas from the above variety. The seed was sown in 8-inch pots on January 16th, and placed in an early vinery until the plants came into flower, after which they were removed to the front stage of our early Peach house. There they have abundance of air night and day, and promise to afford several dishes. My employer pronounced their flavour excellent. I find they are as easy of culture as French Beans, the only difference, in fact, being the Peas need more air than the former. I do not call attention to this as being an extraordinary achievement, as others, including Mr. Barker of Hindlip, have accomplished the same thing, but my object is to point out the superior merits of this dwarf Pea for early forcing. Everyone with a vinery or Peach house may with very little trouble command a few dishes of Green Peas at this time of year.—T. W. SANDERS.

NOTES ON ORCHIDS.

FUMIGATING COOL ORCHIDS.—I am of opinion that slight fumigations of tobacco smoke, provided the material used for that purpose is good, will not prove injurious to cool Orchids. Many good growers fumigate freely, but I do not consider it a wise or a safe practice. What will suffer from fumigations of tobacco smoke sooner than *Cœlogyne cristata* or even *Disa grandiflora*? but the latter is not affected if the application is not too strong. I should say the fumigation given to "W. W.'s" plants has been the cause of injury, for I once saw some fine healthy plants affected in the same way by an overdose of smoke. I have discontinued subjecting my cool Orchids to tobacco smoke, and have found the plants have done better since. Aphides are the greatest enemy to these plants, and some attention is needed to keep the plants free even when tobacco is employed. I obtained a spray distributor and insert it into a bottle filled with a weak solution of tobacco water or Fir-tree oil. The former I prefer, although the latter is the cleanest. This is a ready way of destroying aphides, and does not occupy much time than fumigating.

YELLOW THRIPS.—This is the most destructive little pest the Orchid grower has to deal with, as it makes serious ravages on *Aerides*, *Vandas*, *Cattleyas*, or any other Orchid. It is very difficult to eradicate, and if this is attempted by the aid of tobacco smoke alone much injury would be done to the plants before it could be destroyed. A few years ago it was brought here upon some newly purchased plants which were stood amongst others and unnoticed; it soon gained a good footing. The course alluded to was adopted, but did not prove satisfactory, so other means were tried, which proved successful. A number of small camel-hair brushes and a jar of nicotine soap were

obtained, and three or four men commenced sponging them with a weak solution. One man followed with one of the small brushes, and applied the solution liberally to the axils of the leaves where it is impossible to place the sponge. All the plants, whether any thrips were upon them or not, were so treated; and before the solution had time to dry it was drained out, the plants washed with clean water and stood in a clean house. When all had been done the house was thoroughly cleansed and heavily fumigated two or three nights in succession, and then the plants returned to their former position. As they were brought back they were dewed with the syringe, and tobacco powder applied by means of a distributor. This was left on for about two days and then washed off. This did not exterminate all this troublesome thrips, but we dressed the plants frequently for a time at short intervals and eventually exterminated it, and have never been troubled since.—SCIENTIA.

ORCHIDS AT FERNFIELD, BRIDGE OF ALLAN.—Dr. Patterson sends us a box of beautiful Orchid flowers, which abundantly prove by their size, strength of spike, and rich clear colours how well his system of culture suits them. Of *Lycaste Skinneri* a dozen blooms were sent, all distinct varieties, differing in the size of flower, breadth of sepals and petals, and depth of colour in the lip. In some the sepals are pure white, the petals flushed with rose, and the lip rich crimson with a central white stripe and a few spots; in others the sepals are tinged with rose, as well as the other portions of the flower; in a few the lip is very faintly tinted, nearly white, but the more highly coloured forms predominate. *Odontoglossum Halli* is represented by a very strong spike of eleven handsome flowers, large and heavily mottled with dark brown—a superb variety. *O. Halli leucoglossum* is a lovely variety with a pale yellow ground colour, the sepals and petals bearing towards the apex broad circular brown blotches, but near the base are a series of narrow oblong bars; the lip is white with a yellow fringe at the base, and two or three brownish spots. The contrast of colours in this variety is most pleasing. Of *Odontoglossum triumphans* a magnificent variety is sent, the spike bearing nine large and richly coloured flowers, very suggestive of *O. grande*. The flowers are $3\frac{1}{2}$ inches in diameter, the petals three-quarter inch broad, deep golden yellow, with numerous rich brown spots and blotches; the lip is $1\frac{1}{4}$ inch long and three-quarters broad, pure white at the base, and brown at the tip. It is one of the finest varieties we have seen. *Cœlogyne ocellata maxima* is distinguished by its large flowers, $2\frac{1}{2}$ inches across, pure white, except for the yellow-tinted lip. *Rodriguezia planicaulis* has pale greenish yellow flowers, very small, with wavy sepals and petals, but pleasantly fragrant; and *Chysis bracteosa* is represented by a spike of six ivory-like flowers. Such a choice collection as this is always most welcome, and considering the distance the flowers had travelled their freshness was surprising.

ODONTOGLOSSUM PESCATOREI.—At one of Mr. Stevens' sales last week a grand specimen of this beautiful Orchid was offered, and after some competition was sold to Mr. W. Bull for twenty-five guineas. This plant is reputedly the finest in Europe, having been in the Trentham collection for seventeen years, and is thus really a genuine specimen. It is in most robust health, with six panicles, comprising a total of 180 flowers, not individually large, but of good general outline; the petals broad and rounded. It was much admired at the King Street rooms, and will form an attractive feature in Mr. Bull's nursery for some weeks.

SPECIMEN PHALÆNOPSIS SCHILLERIANA.—At one of the recent meetings of the New York Horticultural Society a magnificent specimen of the above Orchid is said to have been shown from the garden of Mr. Dinsmore at Staatsburgh. According to the Secretary's note in the *American Gardeners' Monthly* this plant was in superb condition, most healthy, bearing six spikes with a total of 246 flowers. Rarely do we see such a grand specimen in this country.

SALE OF ORCHIDS.—At Mr. J. Stevens' sale on the 9th inst. there was a handsome display of Orchids in flower, the room presenting a beautiful appearance. Several magnificent varieties of well-known Orchids were entered, and the prices were mostly good. A dark-flowered variety of *Cattleya Mendeli* realised $8\frac{1}{2}$ guineas; *Odontoglossum Alexandræ* was admirably represented, one extremely fine rose-coloured variety being sold for 24 guineas; and another, also distinguished by its large symmetrical flowers, fetched 14 guineas. A fine specimen of *Odontoglossum Andersonianum* with six flower spikes was sold for 10 guineas; and an unusually beautiful variety of *Dendrobium Jamesianum* realised 15 guineas. A small plant of a large-flowered dark-coloured *Odontoglossum vexillarium* was sold for the long price of 26 guineas, a striking instance of the value attached to fine varieties, for good plants of fair forms of this *Odontoglossum* are sold at a less number of shillings than this one realised guineas. In addition to these the wonderful specimen *Odontoglossum Pes-*

catorei already noted was included in this sale, with many other rare or choice varieties.

PRUNING DENDROBIUMS.—Judging from the animated discussions which have taken place lately, the subject of pruning Dendrobiums is likely to become a favourite theme. The real question at issue is, "Whether it is prejudicial or not to the health of the plants to remove old spent pseudo-bulbs annually." I have no hesitation in saying as the result of my experience that this removal is not prejudicial, but, on the contrary, is really beneficial. Of what possible use can old withered pseudo-bulbs be in either storing up sap or nourishing the young growths? Surely if we reason by analogy it cannot be more injurious to Dendrobiums than to Hydrangeas or similar plants where the growths that have flowered are cut away to make room for the new ones. The statements of some of the controversialists that the old pseudo-bulbs are necessary to support the young growths is incorrect, as I have proved from experience similarly to "B., Sussex." Dendrobiums have a bountiful supply of roots wherewith to absorb the food necessary for the support of the young growths without depending on the pseudo-bulbs.

My experience of pruning Dendrobiums is similar to that of "B., Sussex," except that the current year's growth does not start from the base of the pseudo-bulbs cut away, but from those of last year, which will in the ordinary course flower next season. "B., Sussex," has evidently fallen into error on this point, and it would be well if he stated his mode of pruning Dendrobiums more clearly. We have never yet seen Dendrobiums having growths as fine as those described by "B.," where old pseudo-bulbs had been allowed to remain on the plant.—V.

FRUIT PROSPECTS.

THE prospect of most hardy fruits is very encouraging this year owing to the fine weather. The more delicate wall fruits (such as Apricots, Peaches, and Nectarines) are very promising; the blossoms have been unusually strong and fine, and are setting well. Seldom of late years has such a display of Plum flowers been seen. The size and quality of some of them are remarkable, many of the expanded blooms being nearly 2 inches in diameter. The Pears both on walls, bush, and pyramid trees are flowering unusually well, and the same remark applies to Cherries, Apples, and Gooseberries.

Most vegetable seeds are germinating satisfactorily under very favourable circumstances as regards weather. Potato-planting is well in hand, and the outlook generally is very encouraging. Owing to the late genial showers vegetation is making rapid advance.—A. O. W.

THE SHRUBBERY IN SPRING.

THE first plant to bloom was the lowly *Erica herbacea carnea* followed by *Daphne Mezereum* in February; *D. Fortunei*, with its lilac flowers, coming in at the same time. The first real show was made by the Almonds, their flowers being quite effective at a distance. They show best when treated as standards, and flower most profusely in a light soil as the wood becomes ripened; in fact in a wet soil or cold one the wood is often injured by severe weather and dies back. Similar remarks apply to the double Chinese Peaches (*Amygdalus sinensis alba plena* and *rosea plena*), which succeed the Almonds in flowering, and are followed by the Peaches (*Amygdalus persica*), and are very fine where they do well, but are at best tender, being liable to gum, and trees of large size are rarely seen.

Cornus mascula variegata is by no means despicable, as its bright yellow flowers, which are produced abundantly before the leaves and during the early spring months, ought to secure for it a place in every shrubbery. The Cornelian Cherry is not remarkable after flowering, but the variegated form is one of the finest of hardy shrubs, and is useful both for flowers and foliage. Trained as a pyramid it is very tractable, being kept in shape with very little pruning.

The most showy of the shrubs flowering this year in March were *Forsythia Fortunei* and *F. suspensa* (what is the difference?) the flowers being borne in profusion along the branches and of a bright yellow, and certainly ought to be in every shrubbery. Being of somewhat straggling habit any irregularities of growth can be cut in after flowering, and every encouragement given to form young growths, on which the flowers are most abundantly produced. *F. viridissima* is poor compared with the others, flowering very much less freely, and is not nearly as effective.

Spiraea prunifolia flore plena has pure white double flowers, very freely produced. It forms a somewhat spreading bush about 5 feet in height. The flowers are borne along the branches, and it is of graceful habit.

Mahonia aquifolium, with its bright golden clusters of bloom, is very effective, and is useful for margins and banks, not the least of its attractions being its evergreen character and the profusion of its large purple berries in autumn. *Berberis Darwini* is unquestionably the finest of the family, its rich drooping racemes of golden flowers in contrast with the deep green foliage being very striking. *B. Jamiesoni*, with its pale lemon flowers, is pleasing. *Mahonia trifoliata*, with noble foliage

and large heads of yellow flowers, is well worth a place, giving it a sheltered situation.

Andromeda floribunda forms one of the neatest of dwarf evergreen shrubs, and is mostly covered with its Lily of the Valley-like bells, white and fragrant. It does best in peaty soil, but is not any more particular in this respect than *Rhododendrons*.

Azara microphylla is a neat shrub, its deep shining green leaves and drooping habit rendering it desirable. The flowers are hidden under the foliage, but it cannot fail to please on account of the fragrance. *Ribes* are flowering strongly; they are indispensable, and grow nearly anywhere. *R. sanguineum*, *R. albidum*, and *R. Gordonianum* are the best. The *Ribes* should, from their free-flowering and effective display in the shrubbery, be grown extensively, but not to the extent of precluding others equally showy; indeed, shrubberies should be so arranged as to afford a succession throughout the year. *Kerria japonica flore plena* with its golden flowers is very showy and well worth a place, being as hardy, and does not need the protection of a wall except in exposed situations.—G. ABBEY.

LILIUM AURATUM.

WHY have so many imported bulbs of this Lily perished under cultivation in this country? Various theories have been advanced in answer to this question, and I submit that there has been too much of theory and too little of practice brought to bear upon it. It is neither creditable nor desirable that a difficulty should be suffered to become a mystery, and yet it must be acknowledged that a very general feeling of doubt exists as to the possibility of keeping the magnificent bulbs of *L. auratum* which come to us direct from Japan by tens of thousands every year in a healthy improving condition after the first year. I, for one, must own to having lost every one of a certain number of such bulbs a few years ago; nor was I much surprised at the loss, for the bulbs were planted in newly made shrubbery borders in very poor soil, and left without any particular subsequent care to struggle for bare existence amid a host of all sorts of wild growth which sprang up around them and could not be destroyed until it was too late. This slovenly practice was unavoidable amidst the thousand and one matters pressing upon our attention in a new garden made under circumstances of exceptional difficulty.

In the last number of the Journal of last year I explained in full detail another and certainly a fairer trial with fifty bulbs, which had so far proved successful—that is to say, each bulb had thrown up a strong growth, which had afforded a delightful succession of fragrant blossom for upwards of three months. The bulbs were left undisturbed in the soil and some finely sifted coal ashes spread upon the surface to exclude frost. All of them are now growing so much stronger than last year—most of them having two stems so sturdy and robust, that I feel justified in recording a success which points to still better things in future.

One of the most important points in the cultivation of these bulbs was undoubtedly promptitude in potting them immediately after the purchase, for the flaccid condition of the bulbs then clearly betokened exhaustion from being kept out of soil and exposure to the air. Plunged among and under a bed of coal ashes in a cold frame in pots of moist soil the bulbs soon became plump and firm again, and root-action followed, so that when they were turned out into the borders in March the pots were found to be well filled with roots, and the growth was pushing strongly. The same course was followed with another batch of imported bulbs purchased for this season in case of failure with any or all of last year's supply, and with precisely similar results thus far.

So far, then, as this trial may be taken for guidance in subsequent practice, it shows that the imported bulbs should be purchased as early in the season as possible. Each bulb should be potted separately in a 6-inch pot and forthwith plunged in a bed of coal ashes—not necessarily in a cold frame, but preferably where they can be overlooked occasionally. A rich, porous, well-drained bed of soil should be prepared for them, and they should be turned out of the pots and planted in it early in spring. Once planted they should not be disturbed, and frost should be excluded from the soil by a mulching in autumn of coal ashes or cocoa-nut fibre. Avoid exhaustion of the bulbs by exposure to the air and being kept out of the soil. Avoid planting in poor, thin, or undrained soil; do not plant all your stock in one bed fully out in the open, but plant some in sunny places, some in partial shade, and so prolong the succession of flowers.—EDWARD LUCKHURST.

PURPLE SPROUTING BROCCOLI.—For the past month I have been cutting beautiful tender little heads of this delicious vegetable, and a neighbouring gardener, who has to supply a family of epicures, tells me

it is preferred to Seakale or Asparagus. It seems more delicate in flavour than the white variety, and boils beautifully green. A medical gentleman tells me it contains a larger per-centage of potash salts, so necessary during the spring months, than any other member of the Brassica family. It is a mistake to have it fit for use before the present time. No other Broccoli is hardier than this.—W. J. M., Clonmel.

PENTSTEMONS.

THERE is now a large number of florists' varieties of this beautiful genus, but I do not intend making any remarks upon them in this notice, but will confine myself to the other forms, which for convenience we may call species, that constitute a very important series in the Californian Flora. There is much for everybody to admire in them, but especially are they to be appreciated by those enthusiastic in the cultivation of herbaceous and alpine plants. Some of them it is true are not quite hardy, and consequently it is necessary to keep a certain number under protection during the winter. This may be done by striking cuttings during the summer, or by saving seed, which most of them produce freely; but if planted in a well-drained sheltered position only a few of them will succumb, hence if these species are to be kept it will be necessary to adopt the precaution alluded to. Most of them prefer a light well-drained soil and a sunny position in different parts of the rockery or in small borders. The habit of some is especially suited to the rockery, such as *P. procerus* and *P. humilis*. These are both dwarf-growing and very profusely flowering that they should be in all collections of alpinists forming decumbent shoots, which root freely from the under side, and ultimately produce spreading cushions of evergreen growth covered during the season with their pretty racemes of flowers. The more tender kinds should be planted at the foot of a sunny wall, where they would be protected during the winter; in fact this plan usually affords sufficient protection to keep them alive. I have now good plants of *P. cordifolius* and *P. breviflorus* which have occupied the same position three years, and last season they came up very strong, although cut down by the previous winter, and other plants in the open border were quite killed. *P. Jaffrayanus*, a most lovely species, is perhaps the most tender of all, and it is needful to sow a pinch of seeds yearly or strike cuttings.

No hardy-plant grower has been more energetic than Mr. W. Thompson of Ipswich in the introduction of these charming plants; each season for some years past he has distributed one or two fresh sorts, all of which are well worth growing. I have raised and grown nearly, if not quite, all the Pentstemons which have appeared by name in the various catalogues and collections, and in some cases there have been duplicate names, which of course have been discarded, while other names have been authenticated, and numerous notes have been made upon them during several years. I have often noticed in raising a batch of seedlings that, like all other plants, there is more or less of variation, not so much in the foliage as the colour and size of the flowers, details which botanists should not take seriously into consideration, but which indeed may have been the bases upon which some of the names may have been founded. Seeds of nearly all the species are easily raised in well-drained pots of sandy soil placed in a cold frame or cool house, and if the pots are covered with slips of glass the necessity for watering will be reduced to a minimum, but never allow them to become dry. The seeds of some are very slow to germinate—for example, those of *P. antirrhinoides*, which I have known to remain for five or six months, and rarely more than a few seeds germinate; this may be due to the great length of time which elapses between the gathering and sowing the seed. Other species which I do not now remember have behaved in the same way. Cuttings may also be rooted in pots placed in a cold frame, roots forming in a few weeks, especially if a heel is left to each. I will now give brief descriptions of the species with which I am acquainted, although I am not certain as to the authorities for some of the names; nevertheless they are all distinct and well worth growing.

P. acuminatus, Dougl.—A pretty species, known also under the name of *P. nitidus* of the same author, but well figured under the name here adopted in Lindley's "Botanical Register," t. 1285, and is a native of N. America, being widely distributed throughout the States. It grows from 12 to 18 inches high, with ovate-lanceolate, acuminate leaves, with numerous flowers disposed in a virgate panicle, the corollas being $1\frac{1}{2}$ to 2 inches long, rich purple, with very open throat and large spreading lobes, appearing from July to September. The seed vessels are conspicuously acuminate, upon which character the specific name is based.

P. antirrhinoides, Benth.—A less common species than may be supposed by the name, but is synonymous with *P. Lobbii* of our gardens. It was figured under the latter name in the "Illus. Hort.," 1862, t. 315, and under the name here adopted in the "Bot. Mag.," t. 6157, and near what is described by Lindley in the "Bot. Reg.," t. 1946,

under the name of *breviflorus*. Certainly there is a slight difference in colour, but both are yellow, this plant usually producing clear yellow flowers. Other small deviations may be noted, but I think if a good series of specimens of both were examined they would prove to be identical. It is a copiously branched plant, very leafy, growing from 1 to 4 feet high, with small oblong or oval entire leaves about half an inch long. Flowers solitary, terminating small leafy shoots, with a very broad lemon-coloured corolla about two-thirds of an inch long, with wide gaping lips, a most curiously formed flower. One distinction which is said to be important in the true *P. breviflorus* is that it produces from two to several flowers in racemose panicles, which, however, I have never seen, and it may be after all very doubtful if the right plant is now under cultivation at all. Native of Southern California, flowering in August and September.

P. azureus, Benth.—A beautiful species, widely distributed throughout California, flowering with us from July to September. It grows from $1\frac{1}{2}$ to $2\frac{1}{2}$ feet high, smooth and slightly glaucous throughout, with lanceolate entire leaves and many-flowered racemose panicles; corolla about $1\frac{1}{2}$ inch long, much dilated above, sky blue

Fig. 74.—*Pentstemon cyananthus*.

or blue violet, frequently with a reddish tube. This handsome species is rather tender, and consequently should be planted in a warm position. I have had at least two different plants under this name—one, a very slender-growing and dwarf plant, proved to be *P. deustus*, quite distinct in every way.

P. cyananthus, Hook.—A most beautiful blue-flowering perennial, bearing a spike more than a foot long. It is an inhabitant of the upper valleys of the Plate River, in the Rocky Mountains, where seeds were collected by Mr. Burke. From these seeds plants were reared by Messrs. Lecombe, Pince, & Co., in whose nursery at Exeter the plants flowered in the open air in May, 1849. The species is quite hardy, and a great acquisition to our flower borders. It is desirable to have a succession of young plants always on hand, which may be raised by cuttings early in the summer, and which should be sheltered in a frame during the winter, but with as much exposure as the weather will allow.

P. barbatus, Gray.—This old-fashioned and very showy species is very frequently called *Chelone barbata*, and is highly appreciated; it was figured under this name in the "Bot. Reg.," t. 116, where it is stated that it was introduced from Mexico in 1794 by Sir Joseph Banks. It has a sub-woody rootstock with lanceolate-spathulate leaves, and tall panicles carrying numerous flowers; corolla from 1 to 2 inches long, rich orange scarlet, with a rather narrow tube, and spreading lips. It flowers from June to September, and thrives well either in the border or on the rockery. The effect of its straggling panicles is very pretty upon the rockery. There are slight variations in the plant both in the leaves and colour of the flowers, and these

have been accommodated with the varietal names of *coccinea*, *Torreyi*, and *antwerpensis*.

P. campanulatus, Willd.—A very old and pretty free-growing species, but not often seen now, flowering profusely from April to September; a figure of it occurs in the "Bot. Mag.," t. 1878. It grows from 12 to 18 inches high, with very leafy stems terminated by racemes of flowers. Leaves narrow lanceolate, entire, bright green; corolla about an inch long, light purplish red, with a slightly spreading throat. This grows well almost anywhere, and is perfectly hardy. Common in North America.

P. centranthifolius, Benth.—A handsome and rather scarce species, well represented in the "Bot. Mag.," 5242, flowering with us from July to August, introduced from Southern California, where it occupies open and dry positions. It grows about 2 feet high, is quite glaucous, with ovate-lanceolate sessile leaves and narrow panicles of flowers; the corolla is from 1 to 1½ inch long, tubular, but very narrow, of a bright vermilion scarlet colour, with small slightly spreading lips. I quite think this is tender, although my stock would not allow of any portion being exposed, but I hope to plant out some in spring which will take their chance next winter.

P. Clevelandii, Gray.—This is also a little known but very elegant species, growing from 2 to 3 feet high, with oblong-lanceolate, sharply toothed leaves, and tall slender panicles of flowers on long slender pedicels; corolla rather less than an inch long, sub-funnel shaped, of a rich crimson colour, distinctly two-lipped, with short spreading lobes. Native of California, and but recently introduced, flowering here in August and September, and is extremely graceful in appearance.

P. Cobaea, Nutt.—A very showy though variable species, introduced from the Western States of America about 1835, and figured in the "Bot. Mag.," t. 3465. It grows about 2 feet high, with large lanceolate obtusely-toothed leaves, and stout panicles of large bell-shaped flowers, varying in colour, usually purple and white, sometimes red-shaded, much dilated at the mouth, with spreading lobes. There is also a distinct variety recently introduced, I think by Max Leichtlin of Baden Baden, named *purpurea*, which is a vigorous grower, producing large panicles of deep purple flowers. Any form of *P. Cobaea* is worth growing, and they are quite hardy, flowering from August to October.—PENTAS.

(To be continued.)

NOTES FROM MY GARDEN IN 1883.

GREENHOUSE.

THE query of a correspondent suggests to me that I may as well give my experience of my greenhouse during the past year. With regard to the treatment of that most lovely Orchid *Disa grandiflora*, I have now two pans of it (I use Dominy's Orchid pans), and it is impossible for anything to be more vigorous and healthy than they are. One is filled with a very large number of growths of all sizes; the other contains three fine growths, which will, I hope, all give me five or six blooms and a few smaller ones. I cannot understand how it can be infested with green fly, for I am quite sure no aphid could for a single day withstand the treatment it would receive from me.

As in the cultivation of most plants that require peat, a good deal depends on the character of that used. There is peat to be got in this neighbourhood, but it is so utterly dead and soddened that to use it for potting purposes would be to insure the death of any plant which was treated to it. I once had a lot of *Disa* which I lost, and simply, I believe, owing to the bad character of the peat. This has made me very careful, and of late years I have only used Epps' selected Orchid peat, full of fibre and very sweet and clean. This, with a few pieces of charcoal about the size of walnuts, is all that I use. Some recommend sphagnum to be mixed with the peat; but I have never used it, and as my plants have done so well I think the good old maxim, "Let well alone" is applicable in my case. In potting I fill the pan about half full with drainage, and then put in the peat quite coarse, with the lumps of charcoal inserted here and there in it. I then place the bulbs in it, and fill up; they receive a good watering, and from this time out get a liberal supply of it, given with a syringe. I never go into the greenhouse without taking a syringe and giving it a little. Its native habitat being the top of Table Mountain, on which heavy clouds generally rest, the plant when in a growing state is subjected to continual moisture, and this treatment suits it. I always repot immediately after flowering, when the young growth has started; the pans are then placed close to the greenhouse door, and there they remain until the cold weather sets in. At that time they are removed to the upper and warmer part of the house, so that if there should come a snap of frost for which we were unprepared they might not suffer. As soon as the danger from this is over they are moved to the door again, and there remain until the flowering is over, receiving, as I have said, three or four syringings daily. Under this treatment it is impossible for green fly to exist, and I have never seen one on my plants. The only thing I was ever troubled with was a curious eating away of the epidermis of some of the leaves, which completely browned them. I sent up some of the leaves to microscopists, but got but little satisfaction as to either cause or remedy; however, as they did not seem to injure the plants I did nothing, and they have not troubled me since. Now, all this treatment is very simple, and I am

sure that if these conditions are observed it is one of the easiest greenhouse plants to grow with which I am acquainted; and what a lovely and enduring flower it is! I took one of my plants to a county flower show last year, and six weeks after the same flowers which had attracted much attention there were still fresh.

I am this year trying a few *Masdevallias*, but whether I shall succeed with them is a matter of question. I fear whether the heat in winter will be sufficient for them. At present they look fresh and healthy, but time will show. Another plant on which I pride myself not a little is the *Lapageria*. I have, as I mentioned last year, two plants—one each of *rosea* and *alba*. I planted them last autumn in large pots 18 inches in diameter, and put them on a low stage at the far end of my small house, my object being to train them up at the end and bring them over the central path of the house, so as not to interfere with the plants on the stages, and in this I have thoroughly succeeded. I had at one time between thirty and forty blooms on them as good as I have anywhere seen. It has been sometimes said that they will not bear the sun; but these are in the full sunlight, although it is true the pots are shaded from it. Of course, to those who have *Lapageria* houses, or who can give their plants any room they like, this may appear a very trivial success, as they can probably cut ropes of flowers with as many blooms on them as I had altogether; but none the less, I think many who have been hindered from attempting their culture will take heart of grace from this statement.

Two other trailing plants that I have grown this year are *Clematis oblata* and *Lonicera sempervirens*, but they have been cribbed, cabined, and confined to trellises from which they have every disposition to run away; but, unfortunately, I cannot give them a better place. The former is very pretty, and the latter very showy with its red and orange blooms. It truly deserves its name, for it is never out of bloom when once it starts off. It is deciduous, but all through the spring and summer it is never without flower.

In the little annexe to my greenhouse I have a couple of Grape Vines, and on the wall at the back a *Maréchal Niel* Rose planted in a large pot and trained to run on the back wall. I mentioned last year that I had adopted a plan with regard to the Vines which had been recommended by a suburban amateur, but which I had years before seen with my friend Dr. Samuel Newington at Ticehurst—viz., leaving every alternate shoot and cutting it to about 18 inches in length, and taking the crop from this instead of (as I had been in the habit of doing) from the young shoots of this year's growth, and I promised to chronicle the result. It was most satisfactory. I took quite a hundred bunches of Grapes from them of good size and quality, and I am so well pleased with it that I shall in future grow them in this way. *Maréchal Niel* did famously. It made its growth and flowered before the Vines came in its way, and I had some grand blooms from it, and I see this year that it is still more promising. I am aware, again, that in many these small matters will excite a smile; but for the same reason as I remarked about the *Lapagerias*, they may give encouragement to small men—those who are endeavouring to gratify a taste which they think that their space will not allow them to indulge in. The Grapes would not win a prize at even a local show; but they are very good, and they are always a welcome gift to invalids, and the poor especially prize them.

Although not quite coming under the head of greenhouse, I would like to record a rather successful bit of Tomato-growing which I accomplished in the small pit in which I bloom my *Auriculas*. This is span-roofed; there are two shelves, or whatever else they can be called, on which the *Auriculas* stand, the ordinary soil of the garden, with a layer of gravel or ashes on the top, and a walk down the centre. When the *Auriculas* had finished blooming and had been transferred to their summer quarters the gravel was removed, holes made, in which some good compost was placed, and the Tomatoes planted four on each side. They were as they grew trained up under the glass, and came up over the top. They looked exceedingly pretty, and were very prolific, giving us an ample supply of very excellent fruit. As we cannot in this neighbourhood grow them in the open air successfully, as they get attacked by disease, it was a great matter to have an abundant supply in this easy manner. The pear-shaped variety was very pretty, but I shall hardly try it again, but depend on *Victoria* and *Excelsior*. By-the-by, can anyone give a really good recipe for making Tomato sauce that will keep? There are several given, but if anyone can from experience say that they have found one really good I should be much obliged for it.

There are a few other things which I have found useful in my small house, which I may as well notice. The *Freesias* I have written about before; they are delightfully sweet-scented. I saw them the other day in quantities in Mr. Dickson's in Covent Garden, and they are much used for bouquets. Another very useful flower for cutting is *Doronicum austriacum*. Its bright yellow flowers are very pretty, and as it blooms profusely and bears pot culture well, although perfectly hardy, it is very useful. I have tried *Centaurea cyanus* (the blue Cornbottle) for some time, so as to have blue flowers to cut in the winter; but it is so apt to flag and look shabby that I have determined on not growing it again. The *Schizanthus*, on the other hand, repay one for any trouble taken with them, as they supply a quantity of graceful and pretty flowers during the spring months. On the whole, my greenhouse has been a great success, and has well rewarded us for any pains and trouble we have taken with it.—D., Deal.

FUNGUS IN VINERY.

I HAVE often noticed the correspondents of the Journal recommending leaves as fermenting material in vineries, and I quite agree with

them on that point; but I do not observe them advising their readers to be careful in taking all out when done with. Decayed sticks, leaves, and Beech nuts are very liable to introduce fungus when buried in the soil. In two vineries here it was a practice to bring in leaves for heating material, but for some cause or other the gardener then in charge, instead of clearing them all out again, spread them on the border and covered them with 9 inches depth of fresh loam. The result was when I examined the borders last December I found the layer of leaves a mass of fungus, and we had to open all the ventilators to let the foul air out, as it was unbearable to breathe, so that I should strongly advise persons never to dig leaves in Vine borders.—GEO. MURRAY, *The Gardens, West Ashby Manor*.

INTERNATIONAL HEALTH EXHIBITION, LONDON, 1884. — His Royal Highness the Duke of Cambridge, K.G., has consented to open this Exhibition on behalf of the President, His Royal Highness the Prince of Wales, on Thursday, the 8th of May, at noon.

— As an example of the rapidly increasing demand for Daffodils and their relatives, it may be noted that one grower has within a few days lately sent to market no less a number of the POET'S NARCISS than one hundred dozen bunches, each of which contained twelve flowers, or a total of 14,400 flowers. The variety ornatus is most in demand, and at the conclusion of the recent Crystal Palace Show comparatively small bunches were eagerly purchased at 9d. or 1s. each.

— MR. J. DOUGLAS informs us that in one of Mr. Sweet's vineries at Leyton is a remarkable example of the manner in which scions sometimes affect stocks in the case of a GROS COLMAN VINE GRAFTED ON A BLACK HAMBURGH. The scion has made good growth, but about a foot below the union a strong shoot appeared, which Mr. Douglas states is indubitably of the Gros Colman character.

— A STRIKING proof of the force of the gales in December and January last was afforded at the annual SALE OF TIMBER on the Clumber Park and Worksop Manor estates of the Duke of Newcastle. The catalogue included 2613 trees which had been uprooted in Clumber Park, and 673 trees and 159 poles blown down in Worksop Manor. Among these were between 600 and 700 Oaks, many of noble dimensions. No previous storm has ever proved so destructive in the district.

— BY some mistake a passage was inserted in Mr. Mangles' description of *Rhododendron Fortunei* at page 270 for which he is not responsible. It is stated that the flower of this species is *superior* to that of *R. Griffithianum*, whereas his opinion is exactly the reverse.

— MR. W. W. BROWN, late head gardener to Frederick Priestman, Esq., Elleron Lodge, Pickering, has become the tenant of the old-established nurseries at Whitby, Yorkshire, lately occupied by Mr. H. K. Williamson, and which will be carried on under the style or firm of "W. W. Brown & Co., Nurserymen and Seedsmen."

— THE LAMBETH AMATEUR CHRYSANTHEMUM SOCIETY will hold their tenth annual Exhibition in the Hawkstone Hall, Westminster Road, on November 11th and 12th of the present year. The schedule enumerates similar classes to those of previous years, and all exhibits except those from honorary members must be grown within a radius of a mile and a half of the Elephant and Castle.

— THE *Gardeners' Magazine* remarks that they have been "honoured with an official invitation to a meeting of the Royal Horticultural Society at the Linnean Society's rooms on Tuesday, May the 8th," but that the subject of discussion and year when the meeting is to take place are not named. This is certainly a little mysterious, as we are not aware that any such meetings have been projected by the Royal Horticultural Society this year.

— A KENTISH correspondent writes:—"As an instance of the PAST MILD WINTER we have a Camellia in bloom out of doors. I do not know the variety; the bloom is white striped with red. It is growing in a sheltered niche against the west side of the mansion.

Strawberries are in bloom, and also a large plant of *Souvenir de la Malmaison* Rose growing on the same aspect as the Camellia."

— IN many gardens the profusely flowering *MAGNOLIA CONSPICUA* is now in handsome condition, but some of the best specimens we have seen this season are at Leigham Court, Streatham. They are growing against a wall with a southerly aspect, and the branches have been crowded with snowy flowers for some time. For early spring flowering this tree is unequalled, and it might be advantageously planted much more extensively anywhere in the south of England.

— IN the same garden is an extremely pretty COOL FERNERY, which for naturalness of arrangement and the healthy appearance of the plants could not be surpassed. It is of moderate size, span-roofed, with a northern aspect, the walls being 8 or 9 feet high, and the length perhaps 50 or 60 feet. No attempt is made at elaborate rockwork design, but a few large blocks of tufa or sandstone are employed, the path rising by a few steps to the centre, where there is a small pool, crossed by a stone bridge, a waterfall at the back imparting a pleasing diversity to the scene. The walls are covered with a dense growth of *Ficus repens*, the lower stones being overgrown with *Selaginellas*, larger specimens of *Adiantums*, *Aspleniums*, *Dicksonias*, &c. Occupying suitable nooks or prominent positions *Dicksonia squarrosa* is particularly handsome, its rich green fronds being very strong; while on the back wall *Begonias* of the Rex type and *Nephrolepis* succeed most satisfactorily. All indeed are in admirable condition, and, like every other department of this establishment, afford the best evidence of the attention they receive from the experienced and energetic gardener Mr. E. Butts.

— THE value of *GARDENIA FLORIDA* is widely recognised in gardens, but we have never seen a better example of what excellent results can be obtained in a comparatively small space than that afforded by a house under the charge of Mr. Howe at Park Hill, Streatham Common. There, a division of a range of span-roof pits, about 12 feet square, with a central path, and a bed on each side, is devoted to *Gardenias*, which are planted out, and evidently succeed as well as could be wished. Flowers were cut the first week in March, and the supply will be continued through the greater part of the summer; at the present time the compact sturdy bushes are loaded with buds and flowers of inestimable value. The chief aim is to have a succession of young plants, as the old specimens are found to be less satisfactory than more youthful vigorous plants, as with liberal supplies of water and a good temperature no difficulty is experienced in obtaining abundance of well-formed exquisitely fragrant blooms.

— THE BATH AND WEST OF ENGLAND SOCIETY announce that their meeting for the present year will take place at Maidstone on June 2nd, when the following prizes will be given for horticultural productions. Two silver cups will be given for Orchids—viz., a £10 cup or money for the best group, and a £5 cup or money for the best specimen. Two cups or money will also be given for vegetables and fruit—viz., a £5 cup or money for the best collection of vegetables, and a similar prize for the best collection of fruits. This portion of the Exhibition is as usual under the superintendence of the Steward, the Hon. and Rev. J. T. Boscawen, Lamorran, Probus, Cornwall.

— WITH much regret we have to announce the death of Mr. JAMES ATKINS of Painswick on the 2nd inst. at the good old age of 82. Forty years ago Mr. Atkins was a prosperous nurseryman at Northampton, and retired to Painswick in Gloucestershire, where in private life he cultivated for pleasure the plants which he most loved. These were principally what are called herbaceous plants and alpine. His name will be perpetuated by the pretty little *Cyclamen Atkinsi*, which he raised from seed.

— MR. WILLIAM PAUL has sent us from his Waltham Cross nursery a box of blooms of the CLOTH OF GOLD ROSE. Anything more charmingly beautiful than such flowers as these, relieved by the dark green foliage that this Rose produces, it is difficult to imagine. Though lacking the rich golden colour of the *Maréchal Niel* they are not less attractive, the primrose deepening to yellow having a most pleasing effect, while the expanding blooms are faultless in form.

— MUCH surprise was expressed at Kensington last week that the Floral Committee omitted to certificate the beautiful *AMARYLLIS ADELINA PATTI* shown by Messrs. J. Veitch. This is undoubtedly one of the most distinct in colouring that has yet been obtained, and at the present time the only scope for *Amaryllis* improvers is in increasing

the variety of tints, and breaking as much as possible the uniformity of scarlet and crimson shades that are so abundant. The flower is perhaps not quite so perfectly formed as in many other Chelsea varieties, and one objection raised against it was its angular outline; but this would scarcely hold good, as a certificate was given for one equally as angular and by no means so distinct. The body colour is a peculiar but pleasing dark shade of rosy crimson, slightly broken into irregular broad stripes, the margins and tips being white, constituting a bold contrast. It will certainly make its way in popular favour, and will probably become the parent of a handsome race of novel varieties. Two of the most experienced florists on the Committee expressed a very decided opinion in its favour, but they were out-numbered.

— AS a TRIO OF EARLY RHODODENDRONS the following are undoubtedly worthy of notice, even if their names are seldom recorded in current garden literature:—Nereus, dark maroon or claret colour with white stamens; Russellianum superbum, light crimson; and Prince Camille de Rohan, blush with prominent chocolate spots. In Mr. McIntosh's unique collection of hardy Rhododendrons at Duneevan those named are the only varieties in full beauty, and the trusses are as fine, fresh, and effective as if flowering in June. They are thus hardy as well as attractive, and their condition also shows that the weather, although not genial of late, has not been excessively inclement.

— THE display of HYACINTHS IN BEDS in the same garden has been extremely fine, even perhaps richer than ever, by the freer intermixture of the deeper colours, notably reds. Some 5000 bulbs are planted about 8 inches apart in the proportion of one-third of double and two-thirds of single varieties, the effect of this assortment being more massive than if singles alone are employed. Each truss neatly secured to its galvanised wire stake, and all the beds margined with the arching foliage of Crocuses, produce an appearance at once rich, chaste, and unquestionably beautiful. All who have the honour of the acquaintance of the owner of Duneevan will rejoice to learn that his illness is less pronounced than it has been for some months past. The absence of such an earnest horticulturist creates a blank at South Kensington, and everyone will be delighted to see him in his place amongst the flowers and on the Council board once more.

— A COLONIAL paper referring to AUSTRALIAN TOBACCO states that in New South Wales Tobacco is profitably grown in the north from the Hunter to the Tweed Rivers, ten miles back from the creek; to the west in a line from Tamworth to Dubbo, taking all the country to within ten miles of the coast; and to the south from Albury to Goulburn; in fact, Tobacco can be well grown in the greater part of the colony. The yield is from 1200 lbs. to 2000 lbs. per acre, the market value being from 5d. to 1s. per lb.

— GARDENING APPOINTMENTS.—The following appointments have been made through Messrs. John Laing & Co., Forest Hill:—Mr. Ch. Catchpole, late gardener to R. W. Relfe, Esq., Meldon House, Ravensbourne Park, as gardener to Miss Fanny Hill, Acacias, Dulwich; Mr. Blackburne, lately at Snowden, Ryde, Isle of Wight, as head gardener to Jas. Scott, Esq., Elmstead Grange, Chislehurst; Mr. Messenger, as gardener to Henry Waters, Esq., Langley Lodge, Beckenham; and Mr. McIntosh as gardener to T. W. Lawrence, Esq., Oakleigh, Beckenham.

— MR. JOSEPH MALLENDER sends the following SUMMARY OF METEOROLOGICAL OBSERVATIONS AT HODSOCK PRIORY GARDENS IN MARCH:—"Total duration of sunshine in the month 91.8 hours, or 25 per cent. of the possible duration; we had six sunless days. Total fall of rain 1.50 inch; maximum fall in twenty-four hours, on the 3rd 0.42; rain fell on nine days. Mean temperature of the month 42.7; maximum on the 16th, 68.4; minimum on the 1st, 24.1; maximum in the sun on the 16th, 114.2; minimum on grass on the 26th, 19.1; mean temperature of the air at 9 A.M., 42.2; mean temperature of the soil 1 foot deep, 42.6; number of nights in which the temperature was below 32° in the shade, nine; on the grass, twenty. Highest reading of the barometer on the 27th, 30.258; lowest reading on the 10th, 29.135. Wind has blown from all the points. Average velocity 9.8 miles per hour; it exceeded 400 miles on four days, and one short of 100 miles on five days. The temperature recorded on the 16th is higher than in any of the previous eight Marches, and has not been recorded in April since 1876. The mean temperature is nearly 8° higher than last year; sun-

shine less than in either of the last three years; vegetation forward, fruit blossom abundant."

LIQUID MANURES.

MAY I ask you to take up the subject of liquid manures in the Journal at your convenience? Frequently a certain quantity of guano or some other product of extremely variable composition is directed to be added to a gallon of water with the result of yielding a liquid of unknown strength, and though a skilled gardener may make clever guesses and achieve success with such materials, others are simply in the dark. For two years I have used a mixture containing a quarter of an ounce of nitrate of potash (from the chemist), half an ounce of phosphate of soda, and a quarter of an ounce sulphate of ammonia (ordinary commercial from the manure dealer) to each gallon of Edinburgh town water (containing lime to 5° or 6° of hardness). When this mixture is freely used Cinerarias become vigorous with deep green leaves, and flower for weeks; and it evidently is not too strong for them and other soft plants. Thirty-two gallons is a convenient quantity to mix at one time. I find ordinary gardeners quite helpless when asked questions on matters beyond their own personal experience, and therefore hope that you will discuss the question of feeding plants with ready prepared food without trusting to food resulting from decomposition of the potting materials.—A CONSTANT READER.

THE HERBACEOUS BORDER.

AFTER an unusually mild winter it is perhaps remarkable that most hardy plants, forward as they are, are not in a more advanced stage of growth. True, some have flowered quite out of season, but these are exceptional and do not call for any particular comment.

Of the flowers that have been with us in March, and are at its close mostly over, I may mention Snowdrops, Scilla sibirica, Helleborus niger, H. maximus, and Crocuses. The last have been very beautiful, it being quite unaccountable why they are not more generally planted. Planted amongst grass that is not mown very early, so that they have time to complete the growth before the grass is cut, as is common enough in woodland walks, they are indescribably charming, their bright gold and silver and purple being matchless when seen in the green sward. I suppose we shall in time get clear of the bare-earth system of displaying these, with Snowdrops and Daffodils, and have them clean and bright as we find them naturally.

Primroses have been flowering since the new year, but they were not really good until March. The double varieties of Primula acaulis have been beautiful, and still are so, as they bloom for a lengthened period, and are far more enduring than the type, and much as I like the single varieties I consider the doubles are more effective. The double white, double crimson, double yellow, and double lilac are very bright and pure in colour, and the flowers are perfect rosettes. Double rose, purple, sulphur, and plum are not so clear in colour, being somewhat dingy, yet the double plum has large flowers, is very free. It is identical with Primula acaulis platypetala plena. One noticeable feature about them is that the birds do not pull the flowers to pieces, as they do those of the single varieties and Polyanthus.

Primula denticulata capitata with its large Auricula-like foliage, covered with golden farina on the under side and on its stems, has been very fine with its large close globular umbels of purplish violet-blue flowers with yellow centres, and is now (the close of March) over. P. viscosa nivalis is just expanding, its pure white fragrant flowers on stems just rising above the foliage being very pretty. In charming contrast to all the Primulas is the really lovely P. rosea, which is of free though miniature growth, appears to increase rapidly, and in a mass must be very effective. As it is, it is a gem; the flowers are borne eight or more on a stem a few inches high, in bud are bright crimson, and when expanded a very bright clear rose.

Arabis albida with its sheets of white flowers has been gay all the month. It is very much visited by the bees, and appears to be well worth growing, if only for their use, yet it makes a sheet of telling white flowers either on rockwork or in the border.

Aubrietia græca as a rounded tuft or clump tells well in the herbaceous border, its profusion of bluish-purple flowers rendering it very effective, and is fine for spring bedding.

Anemones of the stellata and coronaria section are unquestionably the most effective of all the flowers in the herbaceous border during March. Shades of blue, purple, lilac, white, scarlet or crimson, and an admixture of colour producing a splendid effect, and for cutting the flowers are superb. All they want is to be planted and left alone, so as to grow into masses, and the more mixed they are the finer the array. A. apennina with its bright blue flowers is charming, especially

so when associated with its white variety *A. apennina alba*, the plants when established being smothered with flowers.

The Megaseas (*Saxifragas*) are just showing their spikes of bright rose flowers from the large cordate leathery leaves, the best of these being *M. cordifolia purpurea*, rich purple flowers on stems a foot or more high, but it flowers a little later than the species, and so does *M. Stracheyi* with its spreading panicles of white flowers, contrasting finely with the purple of *M. cordifolia purpurea*.

Narcissus with me are yet confined to *Pseudo-Narcissus*, *Pseudo-Narcissus plenus*, *Telamonius plenus*, *nanus*, *cernuus*, *obvallaris*, *lobularis*, and *minimus*. *N. incomparabilis Stella* was the first in flower, closely followed by *N. incomparabilis* with its large primrose flowers and sulphur crown; the Butter-and-Eggs (*N. incomparabilis aurantius plenus*) is also in flower, and so are *N. incomparabilis plenus* and *N. incomparabilis sulphureus plenus* (Codlins-and-Cream). The double forms of *N. incomparabilis* are amongst the best of the *Narcissus* for cutting. The finest yet out is *N. bicolor Horsfieldi*.

Hepaticas have not been good. They evidently need more moisture than we have had this winter, yet the double blue has flowered and still is flowering very freely; the white has flowered well. *Hepaticas* apparently need a stiffer and moister soil than ours, which is light overlying gravel.

Spring Snowflake (*Leucojum vernum*) flowered early in March, and were very poor indeed, and were soon over. The finest display we have had so far have been and are *Hyacinths* in beds of imported bulbs; yet those in the borders left undisturbed have bloomed well, forming useful and effective clumps. *Tulips* also are just coming in. Herbaceous borders in the early part of the year are very dull; indeed, without bulbous plants are shorn of half their attractions and usefulness.

Wallflowers which have been in flower for a long time are now at their best. The dark crimson and new dwarf yellow are the most useful. The doubles from seed are weedy—a long way behind the good old double yellow and double purple. For some unaccountable reason our plants of *Cheiranthus alpinus* and *C. Marshalli* have collapsed.

Myosotis dissitiflora grows into a great clump, and is very effective; its comparatively insignificant flowers tell only or best when they lose their individuality in the mass. On account of its innumerable flowers it is a far more effective plant than *Omphalodes verna*, the flowers of which, though larger and bright blue, are not freely produced.

Corydalis bulbosa and *C. bulbosa purpurea* have elegant foliage, and are pretty in the shrubbery border along with Winter Aconite, Snowdrop, Scillas, Daffodils, Primroses, and Violets; but such flowers tell best when seen in a semi-wild state growing in profusion with *Anemones*.

In the matter of foliage there is yet nothing very striking. *Valeriana Phu aurea*, with bright golden foliage, is conspicuous, and unquestionably the best of all yellow-leaved plants for spring bedding. The marbled and very handsome foliage *Cyclamen hederifolium* is certainly effective, much more handsome than many plants grown for their foliage, and might be employed with advantage as an edging to beds of bulbs. Variegated Comfrey (*Symphytum officinale variegatum*) with one-half the leaf—the centre—beautifully green with broad yellow margins, is not surpassed for effectiveness during the spring and early summer months by any other variegated plant in existence. Then for silvery foliage, large, bold, and stately, we have *Centaurea babylonica*; and for graceful foliage and feathery highly divided aspect and majestic proportions during the spring and early summer months we have in *Ferula communis* one of the grandest of foliage plants, the three last being very beautiful in front of shrubberies where they can have liberal treatment.—G. A.

SCHIZOSTYLIS COCCINEA.

MR. WILLIAM HANNAH, gardener at Oakholme, has lately read a short paper upon the *Schizostylis coccinea* at the last meeting of the Sheffield and Hallamshire Gardeners' Mutual Improvement Association, which paper I now enclose. Mr. Hannah grows this plant better than I have ever seen it grown elsewhere. I have frequently seen as many as thirty spikes of bloom on one of his plants in a 10-inch pot.—W. K. WOODCOCK.

"The *Schizostylis* is a plant which I have long appreciated, and I think it must become an established favourite in our collection. I do not know anything more striking than well-grown examples, nor anything more simple than the method of cultivating them successfully. The *Schizostylis* is a native of Kaffraria, and belongs to the order of Iridaceæ or Iris family, and was first introduced in this country in 1864. In 1866 I purchased three small plants, which I have successfully cultivated ever since. It is of a very easy culture, on which account perhaps it is often

neglected, and the result is that the beauty of the plant is not half developed. I will now describe the method which I have adopted in cultivating it successfully. First I procure some good rich loam that has been taken off a rich old pasture, with good cow manure that has been well decomposed, some leaf mould, and well-washed sand. The plants should be rested in a cold pit or greenhouse until the end of March where there is sufficient heat to protect them from frost, but do not let them get too dry or they will probably be injured. About the first week in April is the best time to repot them. If the plants are strong and well grown turn them out of the pots, and divide it with some sharp instrument, which is much better than shaking them out. Place them in the same sized pots (probably 8 or 10-inch) again, and return them to the same atmosphere for three or four weeks. About the first or second week in May if the weather permits remove them to the open air, and plunge them in clean ashes in a sheltered situation.

"The compost should consist of two parts loam, one part cow manure, one part leaf mould, and a small quantity of clean washed sand. Let this be well mixed and remain in a heap for a few days before it is used. Clean pots are essential; I always make it a point to have all pots washed before using them. Let these pots be well drained, some good fibrous loam is best to place upon the crocks, and have the soil made firm about the roots. A potting stick is used to press the soil with, and a good watering is given to settle the soil well about the roots. After that, or when the plants have begun growing, give them a little weak liquid manure twice a week.

"In the first week in September remove them into a cold frame, and let them remain until about the first or second week in October, then remove them into a greenhouse or vinery where they are protected from frost. For the conservatories and greenhouses the *Schizostylis* is a great acquisition when arranged with the *Chrysanthemums* and *Primulas*, and they give a good effect during the dull days of autumn."

MANAGEMENT OF IVY ON WALLS.

ALTHOUGH this subject was brought before the readers of the *Journal of Horticulture* some months ago, the only apology I have to make in alluding to it again is to point out that now is the time for planting and attending to established plants growing on the walls of dwelling-houses and other buildings. I have frequently heard opinions expressed that Ivy is a bad covering for walls, and that it causes dampness; but I can say from long experience that if I had a damp wall to deal with I should not hesitate to plant Ivy as a corrective, and to walls of a perishable nature, such as soft red bricks or sandstone, or any unsightly wall, it is a decided improvement to cover them with Ivy. For some years I have had much Ivy to manage, which enables me to speak with some authority. If not kept in bounds it will soon prove destructive to the roofs of buildings. It must not be allowed to go farther than the space it is intended to cover, nor allowed to enter the roofs of any buildings, no matter what the materials may be. The way we manage our Ivy is to clip it close in annually in March. Before the young growth begins it is of great importance that it should be cut 3 or 4 inches below the roof or eaves, and the only care that is required during the remaining part of the year is to look occasionally round the tops of the walls to see that no young shoots are stealing a march on forbidden ground. After the Ivy is clipped we brush it well down with a half-worn besom to remove dust and any dead leaves. I may add that many of our cottages are of a rustic character, thatched with reeds and other materials, in which sparrows build; but here they are in a great measure defeated, as we use sparrow-proof wire netting on the ridges, gables, and eaves, and owing to the Ivy being so closely cut we seldom find a sparrow's nest in it. Neither is it a harbour for vermin, as some people imagine, when it is kept in the way described.

There are many varieties of Ivy grown, but for general purposes we do not find any better than the Irish Ivy. Newly planted Ivy for covering walls, palings, or wirework will require a little assistance in training until the allotted space is covered. Most nurserymen supply Ivy specially grown in pots, which can be removed and planted without any risk of failure at almost any time of the year. If the weather should be dry or hot at the time of planting occasional waterings will be necessary until the plants are established.—A. O. W.

GRAFTED ABUTILONS.

DURING the spring of 1883 we had a number of seedling Abutilons of the *Boule de Neige* type raised the year previous; and finding they were not all of sufficient merit to pay for the time or trouble of potting, besides taking up valuable space inside, they were, as usually is the case, doomed for the rubbish heap. Upon second thoughts we decided to graft some other variety more useful on these clean, healthy, straight stems; and accordingly set to work taking off the tops of these seedlings, leaving the stocks from a foot to 18 inches high. They were then placed in a gentle heat, sufficient to encourage the flow of sap, to insure its rising well. The bark was then separated all around the top of the scion, and three or four healthy terminal shoots of *Abutilon vexillarium* about 3 inches in length were inserted and firmly bound in with raffia, care being taken to place the top side of the graft to the inside, so that at the commencement of growth they would droop in their natural manner. After this operation they were placed in a propagatium

frame, and in a few days, by their starting into growth, it was perceived that a perfect union had been effected. They were then taken to the intermediate house and carefully shaded for a few days, after which growth became more vigorous. Being carefully repotted and allowed to remain in the same temperature they soon formed perfect heads about 2 feet in diameter, having all the autumn and winter been loaded with their pretty variegated foliage and their handsome pendulent flowers. Plants grown in this manner are invaluable for dinner-table or room decoration, their clear stems allowing an uninterrupted view

was a noticeable want of substance. This variety shows, however, a great advance in many characters. The ground is clear white, the stripes and netting evenly defined, bold, and of a rich rose colour, extremely effective in contrast with the crimson and scarlet varieties. These striped flowers are very useful, as when arranged in a general collection they impart a much-needed lightness and diversity of colouring. Much attention is being paid to these varieties now, and it is highly probable that a considerable improvement will be effected amongst them in future years.

The beautiful new variety named *Adelina Patti* which is noted in

Fig. 75.—AMARYLLIS COUNTESS OF ROSEBERY.

across the table or room, being here much admired for their neat and graceful habit. I would add in conclusion that this mode of growing the *A. vexillarium* type is not so original as I at first anticipated; but to those who have not tried it I trust these few hints may be useful to procure plants that are at once handsome, useful, and cannot fail to be appreciated.—A YOUNG GARDENER.

AMARYLLIS COUNTESS OF ROSEBERY.

THE *Amaryllis* figured in this Journal last week was a good example of the improved *Leopoldi* type, which includes most of the varieties with the best formed flowers. That now presented (fig. 75), is a novelty in another distinct group—namely, the striped or *vittata* varieties, which generally have flowers rather angular in form, and in the earliest departures there

another column is of the same type as *Countess of Rosebery*. Both are from Messrs. Veitch's collection.

SEEDLING OXLIPS.

I SEND by this post a box, which I hope will arrive safely, containing specimens of my seedling Oxlips. At the top is an umbel of the old English Oxlip, then below the moss seedlings raised from the Oxlip and seed saved from Oxlip seedlings. I send a single flower from every plant except three, which are not yet in flower. Four of seedlings produce umbels and single flowers. Would you advise me to save seed from seedlings for another experiment?—A. FITCH.

[Although Col. Clarke stated at the meeting of the Scientific Committee of the Royal Horticultural Society last week that he had often tried to cross the Cowslip with the Primrose but always failed, yet the flowers before us have all the characteristics of both the Primrose and the

Oxlip. Some of the varieties are true Oxlips, others true Primroses, and others again exactly intermediate between the two, both in size, character, colour of the flowers, and the form of the calyx—in the latter respect some being closed, others inflated, while some are in a state of transition. We do not know what you will obtain by raising further seedlings, but we scarcely think you will show more striking examples of the variations of Oxlips as raised from seed.]

THE CONSERVATORY AND ITS INMATES.

(Continued from page 213.)

THE graceful, free-flowering, old-fashioned Fuchsia, a favourite still in thousands of cottage windows and greenhouses, must not be forgotten. Its merits are too conspicuous to be overlooked, and they will be still more apparent if we regard it as an autumn rather than a summer-blooming plant. Old-established specimens which have flowered early if put into a cool well-ventilated greenhouse, or even out of doors in a sheltered place, will bloom profusely a second time, but young plants grown specially for autumn blooming will best demonstrate the worth of the Fuchsia as a decorative plant late in the year.

By the beginning of September the collection of plants in the conservatory will be of a more miscellaneous character; the chief summer groups will have gone or be fading, but there are plenty of successors, and with Balsams, Begonias, Fuchsias, Lilioms, Vallotas, &c., there should be no lack of flowers. In October, however, they are likely to be less abundant; some representatives of the last named may be still lingering, but the floral wants of this time must be met chiefly by plants which have been grown expressly for that purpose. Where the ordinary greenhouse plants prove insufficient recourse may be had to herbaceous and other kinds, which are not usually grown under glass, but which from their hardiness and the late period at which they may be had in bloom can be made very useful at this season. Some annuals, as Collinsias, Clarkias, Godetias, Nemophilas, &c., sown about the middle of June in 6 or 8-inch pots, will make no despicable addition to the conservatory at a time when the supply of flowers is rapidly diminishing. Amongst hardy herbaceous plants I would recommend *Campanula pyramidalis* and *Anemone japonica*. Of the former, both the blue and the white varieties make noble plants in pots, while few flowers are more beautiful than pure white blossoms of the latter. The value of these plants will be fully appreciated where greenhouse room is much limited, as they need not occupy a place indoors until they are commencing to flower; a sheltered corner, or at most the protection of a frame, is all they will require. These, in addition to some of those previously mentioned, supplemented by *Salvias*, *Helichrysoms*, *Browallias*, and others, will bring us to the *Chrysanthemums*. These indispensable flowers will give us another period gay with bloom, but after that comes the most difficult time to provide for—viz., from a little before Christmas till the end of February.

For conservatory decoration in the dreariest part of winter, *Primula sinensis* is perhaps the most to be depended on. The seed to produce plants for blooming at that time should be sown early in February, or, better still, in the previous autumn, in which case the seedlings should be kept in the seed pan during winter, potted singly in spring, and placed in a cold frame as soon as the season will permit without seriously checking them. Place them in the pots in which they are to bloom early in August, return them to the frame, and bring them in the greenhouse about the middle of September, where in October they will commence throwing up their white or crimson flowers, and continue to do so through the greater part of the winter. Treated thus they will not be so liable to be checked by a sudden fall in the temperature as if they had been grown in the greenhouse the whole of the summer. The plants should attain a good size before they are allowed to flower, and they will bloom more freely and at a lower temperature than if they have to make their principal growth afterwards. A few old plants of the previous season, especially of the white varieties, if kept in a shady place out of doors, and not allowed to flower during summer, repotted in August and then placed in a frame till they are well rooted, will be found very serviceable just before the *Chrysanthemums* come in, or they may be retained for blooming later if they are likely to be most required then.

I have refrained from alluding to the *Pelargonium* till now, as although some representatives of the family are to be found in bloom at all times of the year, I have preferred to consider it amongst winter-blooming plants; and whether it is allowed such a position or not, the *Pelargonium* can be made a most valuable auxiliary to the conservatory at that time, which it will light up with a diversity and vividness of colouring not then found in any other species of plant. For this purpose take off cuttings in spring if small plants are required, and in the autumn previous if larger ones are wanted. As soon as they are well rooted take out their growing points and let the side shoots be stopped frequently afterwards that the plants may be kept dwarf and compact. The cuttings should be taken from hard short-jointed shoots which have flowered freely in preference to those which are soft and sappy. Endeavour to avoid a gross rapid growth, which may be partly done by potting firmly and allowing the plants to remain out of doors as long as is consistent with their safety. Do not overpot, as they will bloom more freely if slightly root-bound. Cut down old plants after their spring-flowering is over, allow them to break, repot, place them out of doors till the nights threaten to be frosty, and they will make a brilliant display after being brought inside, but they will not flower so long as the younger plants. By many the *Camellia* will probably be considered first in the order of merit as a winter bloomer. I would, however, offer a word of

warning concerning these aristocrats of the conservatory. In places where in severe weather little can be done in the way of heating beyond the exclusion of frost, they had better not be started early in the season. They are very impatient of a great or sudden change in the temperature when coming into flower, and if they are then subjected to such a check the buds will fall.

Let me here direct attention to the value of *Azalea mollis* for winter work. It forces more readily than *A. indica*; its large *Rhododendron*-like trusses are freely produced, and their soft delicate colouring is very beautiful. *Helleborus niger* is another useful plant at this season, the variety *maximus* being the best. A few pots of *Auriculas* likewise may be made serviceable, as they can be had in bloom any time after Christmas, and some of the varieties are very lovely. The white *Roman Hyacinth*, from the beauty and fragrance of its flowers and the facility with which it can be grown, is most desirable for winter, and should be employed extensively. In addition to the *Bouvardias*, *Chorozemas*, *Ericas*, *Cyclamens*, *Acacias*, *Chinese Plums*, &c., usually employed at this time, there are many other plants designated winter-blooming; but of all of them it may be said that the satisfaction hoped for from them will depend largely on the forwardness and thoroughness of their condition. Hardwooded plants especially should have their buds set sufficiently early to allow them a period of rest before being again started for blooming, and any which may have been placed out of doors should be housed before the cold rains of autumn have chilled their roots. I have passed unmentioned many well-known plants, and cultivated in numbers at most places. It was not necessary to catalogue them here, and what I have named will show the abundance which exists for maintaining a supply of bloom at all seasons, and which will enable us to accomplish this if certain well-understood conditions can be secured. I have also kept chiefly to old and well-known species, as it is on them that we must mainly depend for that supply. It will be observed that I have made no mention of the stove or of stove plants. My reason for not doing so is the fact that there are many gardens which have not the assistance of one, but where such help exists the difficulty of supplying the conservatory with flowering plants is, of course, much lessened.

I have not presumed to lay down any cultural rules differing from those so long established and generally recognised, and which time and experience have proved to be in the main correct. The science of gardening is not a thing of yesterday, and the general methods of cultivation are too well known to need detailing here. There are, of course, little facts which spring to light in the experience of everyone. A few such I have noted, but I have endeavoured to avoid the dry details of cultivation as unnecessary to my purpose, which is to impress upon my brother gardeners what to me seems the importance of keeping the conservatory well furnished with flowers, and I would urge the most strenuous exertions to make that structure attractive at all times. Even in those months when Nature is most prodigal of her floral wealth it should still be turned to as containing the choicest quality, as well as the greatest profusion of bloom; but, in the season when the hedgerows are leafless, and the ground bare and frozen, or covered with snow; when neither the greenness of a leaf nor the brightness of a flower is to be seen out of doors, then the conservatory becomes of increased interest. In many gardens the time when the resources of the conservatory for supplying cut flowers will be most severely taxed will be just after the superabundance of summer. The natural effect of the season's decline will seem to be unnoticed, and there will be no falling-off in the demand; the scissors will be actively employed, and, as is well known, indiscriminate and injudicious cutting can paralyse to a great extent the best efforts of the gardener. In endeavouring to avail ourselves of every aid to the accomplishment of the object I am advocating, that which concentration can afford us should not be despised, and the prudent cultivator will not, especially in autumn, keep the plants which are in bloom scattered through the various structures, but will, as far as practicable, gather up every one, that it may contribute to the embellishment of the conservatory. Re-arrangement also can be made to play no insignificant part. Plants should not be allowed to stand in the same places for a great length of time, and the grouping should be frequently altered. A plant in a new position acquires a new interest, and the re-arrangement of a group or bank gives something of a fresh character to the plants of which it is composed.

In conclusion, I would urge upon my brother gardeners what I deem the desirability of the object here indicated as conducing to their own interests. The prosperity of gardening as a profession does not depend on those colossal establishments which have so deservedly become famous in the annals of horticulture, but rather on the maintaining and multiplying of those small or moderate-sized gardens, the proprietors of which are found chiefly in the middle ranks of society. The gentleman who has a well-stocked conservatory to show his friends may, in doing so, be setting before them an example which some of them may determine to follow. We should remember that the love of flowers is very widespread, and that by such means as I have indicated we, as gardeners, can do much to encourage and develop that love. The spirit of emulation may be excited amongst both employers and employed, present establishments may be enlarged and new ones brought into existence.—GEORGE WINTERBURN, *Westwood Lane, Leeds*.

[The first-prize paper read at the Leeds Gardeners' Meeting.]

RHODODENDRON GLAUCUM.

DURING April and early May this *Rhododendron* is very attractive either in pots or out of doors, as in most districts in the south of England

it flowers regularly and freely every year if moderately sheltered. Though less conspicuous than many of its taller relatives, yet as a margin to large beds of Rhododendrons or other shrubs it is most valuable; and when in good condition in such situations is invariably admired.

The species is a native of the Sikkim Himalayas, where it was found by Dr. Hooker in 1850 growing, as he has stated, on "rocky depressed ridges in Sikkim and Bhotan, 10,000 to 12,000 feet above the level of the sea." Seeds were sent to Kew in 1850, and the first plants flowered there in a cool greenhouse in March, 1853. Plants were also tried out of doors, but did not flower until some time after, though specimens near the cool fernery now flower readily every season. There has thus been abundant time for it to become known in gardens, but it is yet far from being common, though its near relation, *R. ciliatum*, is a familiar plant.

R. glaucum is dwarf in habit, rarely exceeding 3 feet in height, and is usually much less; it is compact, branching freely, and the bright brown branches are well clothed with neat glaucous green lanceolate leaves 3 to 4 inches long. The corollas are bell-shaped, $1\frac{1}{2}$ inch across, shallow, with rounded lobes, and are of bright reddish-rose tint in the bud, but lighter when expanded, sometimes having quite a purplish hue. The flowers are borne in heads of five to eight at the apex of the branches, and are slightly nodding. In a synopsis of the species of Rhododendrons

Fig. 76.—*Rhododendron glaucum*.

found in Sikkim by Dr. Hooker, and published in the Horticultural Society's Transactions for 1852, this species is associated with *R. Dalhousiae*, *R. Edgeworthi*, *R. barbatum*, *R. ciliatum*, and *R. pumilum* in a group which forms the third of a series of eight under which the twenty-eight species from that district are arranged. These are distinguished by the following characters:—"Calyx of five leaves, or deeply five-lobed; corolla, funnel or bell-shaped; stamens, ten or eighteen; ovary, five or six-celled. Trees or shrubs; sometimes epiphyte, with the leaves often covered with small scales."

PRIMULAS.

THIS is without doubt one of the most interesting and at the same time highly decorative groups of spring-flowering plants, being alike valuable for the rock garden, the border, or for the embellishment of the cool greenhouse or conservatory; and being in the majority of instances of comparatively easy culture is at once a strong recommendation, favouring their more extended cultivation. It has upon more than one occasion been contended that some soil or combination of soils must be had for the successful culture of many species; but to lay down any hard-and-fast rule as to soil (which, by the way, only plays one part in connection with the cultivation of a plant) without having regard to situation, altitude, and so on, is an error of not unfrequent occurrence. Still the vast importance attaching to these seemingly minor particulars should receive due consideration in the

planting, not only of the various species of *Primula*, but of all alpine plants which are fastidious as to soil or situation. Take, for example, that lovely species *P. sikkimensis*, which under cultivation in this country is rarely seen in good condition. In its mountain home it inhabits wet boggy situations and attains a height of 2 feet and upwards. Take it without considering the conditions under which it luxuriates in its Indian home, and plant it in an exposed dry position on the rockery, and failure or perhaps death will ensue. Here, then, is a case in point where a plant, being deprived of one of the conditions in which it delights, fails; whereas if the soil was the all-important point this might be supplied it in any position we may choose to place it, but it is not so. Other conditions must harmonise with the soil to insure success. We cannot, it is true, imitate the great elevations at which many plants are found; but this seems the least important condition, inasmuch that the great majority of plants found growing at such great elevations readily submit to lower altitudes, and consequently temperatures equally variable; yet the conditions of sun, shade, or moist-loving should be duly considered, and next to these that of soil. Taken as a whole the genus *Primula* delights in and requires a deep soil, and to this may be added, at least for the strong-growing species, a fairly rich compost. I will not longer dwell on preliminaries such as these, but which, by the way, must not be overlooked, but will give a brief account of some of the most noteworthy species and also the conditions under which they best succeed.

PRIMULA CAPITATA.—A rare and handsome species from the Himalayas and one of the most distinct, having numerous heads of rich indigo-blue flowers borne on mealy stems a foot in height. A profuse bloomer, succeeding in a mixture of loam and peat. The latter should be rough and fibrous, and should be added at about one-sixth to that of loam, avoiding manure unless thoroughly decomposed. In some localities this species thrives and seeds freely in retentive soils. This, however, is the exception rather than the rule, for a partially shady position on the rock, where it will enjoy the cool side of a stone, it will invariably thrive.

P. CORTUSOIDES.—This distinct species hails from Siberia, and is at once distinguished by its soft somewhat downy leaves, which strongly resemble the *Cortusa*, and hence its specific name. Its deep rosy clusters of flowers are borne on stalks from 6 inches to a foot in height, and among the earliest of spring-flowering plants. Care should be taken in planting to fix it in a somewhat sheltered nook in the rock garden where it is safe from biting winds, for though perfectly hardy it is often disfigured by being planted in a position too exposed. It succeeds well in a mixture of equal parts of loam, leaf soil, and peat made fairly rich, and with a liberal addition of good sharp grit.

P. CORTUSOIDES AMENA.—For some time this was believed to be only a variety of the preceding, though a very distinct one; but now it is generally recognised as *P. Sieboldi*, and was originally introduced as *P. amena*, a Caucasian species, which so far as I know has not yet found its way into English gardens. Be this as it may, there is no doubt but that *P. Sieboldi* is destined to become one of the most popular plants for either greenhouse or border decoration. It seems to thrive in almost any situation, and prefers a comparatively rich soil in a moist well-drained situation. While the plant is yet dormant a top-dressing of thoroughly well-rotted manure, leaf soil, or spent hops will be found highly beneficial. This method is preferable to any other for this individual species on account of its spreading habit of growth. It makes a most magnificent bed if allowed to remain undisturbed: its light magenta flowers produced on stems a foot in height have a telling effect. The varieties of this plant are already numerous, and are equally hardy and vigorous as the type. Among the best are *grandiflora alba*, of the purest white; *lilacina*, lilac suffused with white; *intermedia*, similar in colour to the type; and *Ruby*, deep red. This of all *Primulas* is of the easiest culture, and should find a place in every garden large or small.

P. DENTICULATA.—That this well-marked and vigorous species should not receive the attention it deserves at the hands of all lovers of gardening remains a mystery. In it we have a thoroughly hardy and decorative plant of high standing, and those whose attention is so much turned to spring gardening are annually losing a golden opportunity by shutting out a plant so admirably adapted in every respect for that purpose. It may

be had in perfection ere the Tulip dare unfold a leaf and the Hyacinth is yet below the sod. From the first week of March it may be seen with its stout flower stems a foot or more high, crowned with dense umbels of lavender-lilac flowers springing from tufts of oblong lanceolate, toothed, hairy leaves. It delights in a deep rich loam and lasts for weeks in perfection. It is easily and readily propagated by division or seeds. If the latter be resorted to care must be taken not to cover the seeds too deeply; indeed the seeds should be barely covered and never allowed to become dry after sowing, since many failures are attributable to this cause. Already some excellent forms of this plant have been selected from among many hundreds of seedlings, and there is good reason to believe that before long some splendid varieties will be to the fore.

P. FARINOSA.—A slender and interesting native species, varying from 3 inches to a foot in height; stems and leaves densely set with a silvery farina; flowers lilac purple. It requires a damp—almost wet—still well-drained position either on rockwork or slightly raised beds in peaty soil. It is easily reproduced from seed. The seedlings may be dotted about so as to form small colonies, and thus produce greater effect.

P. INTEGRIFOLIA.—A pigmy Pyrenean species, with glistening, entire, ciliated leaves lying close upon the ground, and having handsome rose-coloured flowers, which are borne on short stems scarcely more than 3 inches in height, delighting in moist sandy loam and leaf soil, taking care to plant firmly.

P. MARGINATA.—This is easily distinguished from all others of this genus by the dense silvery margin of its greyish serrated leaves. It is among the gems of the rock garden. Flowers, which are bright rose-violet, form a striking contrast to its powdery leaves. Evidently one of the oldest species in cultivation, and still by no means common. A mixture of equal parts sandy loam and peat suits it admirably. Native of the Taurian Alps, and originally from Switzerland.

P. MINIMA.—A diminutive gem, scarcely 2 inches high, having large rose-coloured flowers, which almost hide from view the small glossy and deeply notched leaves. Whether grown in pots or planted on the rockwork, it must be planted firmly in rich sandy loam; a few small stones about it, staying evaporation, might be applied with advantage. Native of southern Europe.

P. MUNROI (P. INVOLUCRATA).—A distinct species from northern India, growing a foot in height and having creamy white flowers. It thrives well in good ordinary soil in partial shade.

P. OBCONICA.—An ever-flowering species of recent introduction. Its hardness at present is somewhat doubtful, and should receive protection. The flowers are large, white, shaded lilac, and borne in umbels in great profusion.

P. PALINURI.—A most distinct species from Southern Italy of decidedly arborescent habit and easy culture. The leaves and stem are unusually stout and vigorous. It is seldom seen in good condition, and requires to be planted in a deep bed of rich soil. Its flowers are bright yellow, produced in a cluster on the summit of a stout mealy stem.

P. ROSEA.—A lovely new Himalayan Primrose, quite distinct from all others, and a gem for any purpose; of vigorous habit, increasing with amazing rapidity, and quite hardy. In bud the flowers are of a rich scarlet-crimson, but when expanded a clear bright rose. It grows 6 to 9 inches high, and prefers good, rich, deep sandy loam, and without doubt one of the finest Primulas in existence.

Thus I have given a few of the most noteworthy of the species, together with their requirements. There are, however, many more worthy of mention and equally valuable; but notice of these I must at present defer.—J. H. E.

REPORT ON THE PROGRESS AND CONDITION OF THE ROYAL GARDENS, KEW, DURING THE YEAR 1882.

THOUGH somewhat late this production is always welcome, and the present issue contains even more varied and useful matters than usual, in addition to the ordinary reports of improvements in the establishment. Many desirable alterations have been effected at Kew during the past three or four years, and it is a general opinion amongst those who are familiar with the gardens that their condition has never been so satisfactory as at the present time. It is most pleasing to observe this evidence of energy and activity in our national gardens, and still further and greater advances may be confidently expected.

That the popularity of the establishment is steadily increasing is manifested by the following statistics:—

"The number of visitors, 1,244,167, to the Royal Gardens during 1882 was enormously larger than any hitherto recorded. It is 407,491, in fact nearly half as much again greater than the number, 836,676 of the preceding year.

"The number of visitors on the Whit-Monday Bank Holiday, May 29th, was 95,300, the largest number of visitors ever admitted on any single day in the year. On December 1st the Royal Gardens were visited by only twenty-seven persons. The following figures give the total numbers admitted during each bank holiday, and also the numbers of persons who on each occasion entered before 1 P.M."

Dates.	Total Number during day.	Number before 1 P.M.
April 10th	56,676	8,521
May 29th	95,300	12,589
August 7th	75,879	8,600
December 26th ..	1,460	520

Particulars of the planning and cost of the rockery are given in full, but the most important portion of the report is that giving a list of the Palms in cultivation at Kew. Referring to this the following passage may be cited:—

"The elaboration of the order *Palmae* for the 'Genera Plantarum,' published by Mr. Bentham and myself, has led me to a critical examination of the species of Palms in cultivation at Kew. This proves to be of somewhat unexpected richness; a fact which, however, need scarcely perhaps be matter of surprise, seeing that for many years past, in fact since the existence of the Gardens as a public establishment, no pains have been spared to obtain seeds of these attractive plants, for the cultivation of which Kew possesses peculiar facilities, from our numerous correspondents in all parts of the world.

"In appendix ii. I have given a classified list of Palms, 420 in number, at present cultivated in the Royal Gardens.

"The compilation of an accurate catalogue of Palms under cultivation is a matter of great difficulty; owing, partly to the impossibility of determining them till they flower, and partly to the practice that prevails in the nursery trade of attaching provisional names to seedlings of Palms which, though unrecognisable both as to genus and species when in that state, are as full-grown plants well known under older names.

"The Kew collection of Palms is the oldest of any note. It was eclipsed altogether between the years 1820 and 1845 by the famous collection of the brothers Loddiges at Hackney, which in the latter year contained upwards of 200 kinds, but which was dispersed shortly afterwards.

"Now it has but two rivals, a European and Asiatic one—namely, the magnificent collection, made chiefly by Herr Wendland, in the Botanical Garden at Herrenhausen, Hanover, and the Palmetum of the unrivalled tropical gardens at Buitenzorg in Java. The Royal Botanical Garden at Calcutta would doubtless hold rank with these were it not for the destructive cyclones which have on several occasions decimated its contents, and especially struck down its Palms.

"The Kew collection is indebted to all the above-named institutions for seeds or plants of many of the species it contains. It is, however, especially indebted to Herr Wendland, himself an *élève* of Kew, whose knowledge of the order is unrivalled not only for many species, but for valuable information as to their names, affinities, and culture.

"The following statistics give an idea of the progress made in the introduction of Palms into cultivation, premising that before the publication of the first edition of Aiton's 'Hortus Kewensis' only two were generally known in our houses—the dwarf Fan Palm, *Chamærops humilis*, of the Mediterranean, and the Date, *Phoenix dactylifera*, both cultivated in the Chelsea Garden about 1731, and probably earlier elsewhere.

"Palms enumerated in Miller's 'Gardener's Dictionary,' 1731, 7; Palms enumerated in Aiton's 'Hortus Kewensis,' Ed. 1, 1779, 10; Palms enumerated in Aiton's 'Hortus Kewensis,' Ed. 2, 1813, 24; Palms enumerated in Loudon's 'Hortus Britannicus,' 1830, 131; Palms enumerated in Loddiges' 'Nursery Catalogue,' 1845, 210; Palms enumerated in Wendland's 'Index Palmarum,' 1853, 287; Palms enumerated in Botanical Gardens of Buitenzorg, Java, 1860, 273; Palms enumerated in Herrenhausen Garden, Hanover, 1882, 445; Palms enumerated in Kew, 1882, 420."

In the list of names in the appendix it may be observed that the new system of nomenclature for which Herr Wendland is chiefly responsible is adopted throughout. This, though no doubt preferable botanically, is slightly confusing, and it is regrettable that an additional list of the ordinary titles with their new names appended could not have been furnished, as it would have greatly increased the general value of the list. For example, the *Kentias* are much dispersed, *K. Canterburyana* becomes *Hedysepe Canterburyana*, *K. Wendlandiana* is now a *Hydriastele*, *K. Fosteriana* and *K. Belmoreana* being found under the genus *Howea*. *Arecas aurea*, *rubra*, and *purpurea* are placed in *Dictyosperma* with the same specific names. *Arecas sapida* and *A. Baueri* are placed under *Rhopalostylis*. *Chamærops Fortunei*, *excelsa*, *Martiana*, &c., are transferred to *Trachycarpus*. *Pritchardia filifera* is now a *Washingtonia*, and *Rtychosperma rupicola* is a *Loxococcus*. These are only a few examples of the more common species, but it will probably be a long time before the new titles are generally adopted in gardens.

The colonial reports are as usual very full and important, and some of them may be noted in these pages in a future issue.

THE ORANGE IN AUSTRALIA.—The Orange tree was first introduced into Sydney, New South Wales, from Brazil, in 1788. Captain Hunter says, in his "Journal of Transactions at Port Jackson and Norfolk Island," that they took on board at Rio de Janeiro, among other seeds and plants,

"Orange, Lime, and Lemon trees," and further states that at Sydney "Vines, Orange, and Lemon trees are in a very thriving state." These were introduced from Sydney into Norfolk Island, when Lieutenant King observes in his Journal of 1788, at that island, "Two Orange trees, which I brought with me (from Sydney) were kept in tubs until I should find a sheltered situation to plant them in. He afterwards says they were planted in the vale; and in March, 1790, observes, "Vines, Orange, and Lemon trees are in a very thriving state." Thus we find that they appeared to be well established in Norfolk Island; and at this time they were also thriving at Sydney, as we learn from "Phillips's New South Wales in 1790," from which date we may consider the cultivation of the Orange tree as permanent in the colony. Orange cultivation is now a leading industry in New South Wales, its head-quarters being at Parramatta, near Sydney, where millions of Oranges are annually grown both for home consumption and for export. The Orange is also largely grown in other parts of the colony, being in some measure to the colonists what the Apple and Pear are to residents in the United Kingdom.

WALL PLANTS IN SPRING.

JASMINUM NUDIFLORUM has been a mass of golden flowers since the new year, and where there is a background of green, like Ivy, to back it up it is simply lovely, but glare without relief is not acceptable, even in the dull season of the year.

Cydonia japonica still holds its own as one of the brightest and freest of early spring-flowering plants against a wall, where it is well worth a place. In the open it flowers quite as well but later. Alongside our old favourite the new C. Maulei is less effective and more slender in growth, producing its salmon-rose flowers, however, abundantly on last year's wood, and comes in in March. What its fruits may turn out to be is a question of experience, but its flowers certainly do not show to advantage in contrast with a red brick wall.

Very different indeed is Magnolia Soulangeana with its large Tulip-like blossoms, pure white with a purple base, extending up the midrib or feathered up each petal outside, pure white inside. It is really very fine, and flowers very freely, even when not more than a yard high. It flowered about the middle of March, but lasts for some time. M. conspicua superba and M. speciosa are also good, but I think M. Soulangeana the best.

What a dreary aspect have Ampelopsis hederacea and A. Veitchi compared with A. sempervirens, its deep green, small, divided, Vine-like foliage keeping fresh all the winter. This will undoubtedly take a first place amongst wall plants, being very free in growth and so very neat. It does well on a north aspect, and is evergreen.

As an evidence of the mildness of the winter Tropæolum speciosum has not died quite down; some of the young growths are quite 18 inches high, and are now advancing freely from the root. Other plants have died quite down and are only just "budding" from the roots. The plants are of course on a north aspect.—G. P. P.

CYCLAMEN PERSICUM.

At Stumperlowe Hall, Sheffield, the residence of H. J. Dixon, Esq. is now to be seen a remarkable display of Cyclamens. The plants number about fifty, nearly twenty of which will average 2 feet in diameter, and a few are 2 feet 6 inches across. A dozen or more of the plants have 300 flowers each, and on one I counted nearly 500. The largest plants are six years old, and the corms are 9 inches in diameter. They are all good varieties, as only such are grown. A small batch of seedlings are raised annually, out of which a few of the best are selected. Mr. H. Watson, the gardener, who thoroughly mastered the cultivation of this plant, for which he has gained a local reputation, prefers sowing seed in March, and he grows the young plants on rapidly after the manner practised by the London market growers. The compost employed is about three parts of rich leaf soil to one part wood ashes and charred refuse, with a liberal admixture of sand. The leaf mould is prepared as follows:—Fringing the lawn, which is extensive, is a single row of very large Sycamores some fifty years old. The leaves of these trees are annually collected and used as a covering for forcing Seakale in the open garden. A small amount of stable litter is added to the leaves to assist fermentation. After the Seakale is gathered these leaves and litter are together wheeled into a corner to decay, and the drainage from a dung heap is allowed to run amongst them. When sufficiently decayed it is turned out and laid up to dry, and when sufficiently pulverised is used as before stated as the main portion of the compost for Cyclamens. The plants, as will therefore be seen, are grown in a compost remarkably rich in nitrogenous matter and potash.

In potting Mr. Watson keeps the corms well on the surface, and he is careful that the pot across the top shall not exceed the corm in diameter by more than from 1 to 2 inches, as he has invariably found that when such has been the case, the plants, though growing vigorously and making fine heads of foliage, have not been so floriferous. The largest corms, 9 inches in diameter, are growing in 10-inch pots, thus just allowing space in potting to firmly press in the compost round the base of the corm.

Water is very liberally supplied while the plants are blooming. At the time of my visit the largest plants were standing in saucers filled with water. After blooming they are removed to the north side of the house, where they are shaded by large Camellias, and water is much more sparingly supplied. During the summer, from May onwards, they are placed out of doors on the north side of the potting shed, but at no time

are they allowed to become thoroughly dry. One plant has about two-thirds of the flowers pure white, and the remaining one-third heavily tipped at the base of the petals with dark crimson.—W. K. W.

HARDY FRUIT GARDEN.

Sewage.—As the blossom expands a feeling of anxiety arises as to the setting of a full crop of fruit, as one important means to so desirable an end liberal waterings of sewage tend to promote a full strong flow of sap, and thus invigorates tree and plant, and tends materially to a prompt healthy action in root and branch if there is any tendency to dryness in the soil. This may be thought hardly possible in showery April, but the mean rainfall of the month is less than that of either May or June, and the mere surface wetting from a passing shower can hardly affect the roots of a large fruit tree. All bush fruits and Strawberries are unquestionably much benefited now by sewage poured over the entire surface between the rows with a free hand. It is, of course, taken for granted that the land is well drained, for we have repeatedly called attention at the proper season to the importance of this matter as a fundamental rule in fruit culture.

Strawberries.—New Strawberry beds are usually made in the late summer or early autumn months, but it is a moot point if then or now is the best time for doing this. New beds made in August undoubtedly afford an early supply of fine fruit next year, but that is precisely the time when space cannot be spared for the purpose, except in very large gardens. The work is therefore often put off for a month or two till the summer crops are cleared, and then there remains barely time for the young plants to become established in the soil before cold weather sets in. We prefer to secure the earliest runners and at once plant them a foot apart in nursery beds of leaf mould, in which the roots spread quickly and strongly. There they remain till March or April, and we have just finished making extensive new beds with plants so prepared, and which were transplanted with very large balls of the leaf mould bristling with white healthy roots, and with full plump crowns, and plenty of stout healthy foliage. Some of our neighbours have shown their approval of the plan by accepting some of our surplus plants for their gardens, and we strongly recommend it to all whom space and time are much restricted in the busy summer months.

Young Standards.—Standards planted in orchards laid down in grass should have the stems protected from cattle, either by bushes, or, better still, by cradles of iron or wood. Wooden cradles last sufficiently long for the purpose if the post bottoms are steeped in creosote or thoroughly charred in a fire before they are put in the ground. We have seen the bark of such trees when left unprotected so much eaten by sheep in a hard winter that the trees died.

FRUIT-FORCING.

VINES.—Early Houses.—In the earliest house the Grapes are now ripe or nearly so, and where they are expected to keep in good condition some time the temperature should be gradually lowered to 60° at night, and 70° to 75° in the daytime, admitting air freely, employing no fire heat in the daytime. In the case of Hamburgs it will be necessary to afford slight shade from bright sun after the Grapes are fully ripe, as they are liable to become reddish if they hang long. Keep up a fair amount of atmospheric moisture by damping the paths occasionally, and a little ventilation at night will prevent the deposition of moisture on the berries. The inside border must not be allowed to become dry, but should be kept moist, watering if necessary in the morning. Vines that were started in December or January will be taking their last swelling after stoning, and should have the bunches examined, and if any are likely to be crowded a few of the least promising berries must be removed, which will greatly improve the appearance of the bunches and their quality when ripe. The inside border should be given a thorough soaking with tepid water or liquid manure, so as to keep the soil in a moist condition until the Grapes are ripe and cut. The watering is best done in the morning of a fine day, as this will allow the superfluous air moisture to disappear before the house is closed, and to lessen the necessity for further watering mulch the border with a little fresh but sweetened stable manure, the ammonia from which and the liquid at the roots will keep red spider in check; but if the pest appear sponge carefully with an insecticide such as Gishurst or nicotine soap, 4 ozs. to the gallon of water. This is safer than sulphuring the pipes where the delicate-skinned varieties are grown. As soon as the Grapes change colour admit air night and day, increasing it as they become ripe, and gradually reduce the temperature as indicated above for the earliest forced Grapes. Continue a moderate degree of moisture in the house for the benefit of the foliage, not only after the Grapes change colour, but afterwards, as in the early part of the year air moisture is not so much dreaded.

Muscats.—Houses in which these and other shy-setting varieties are in flower will need a high temperature by day, or 80° to 85° from sun heat, 75° without sun, accompanied by a good circulation of air and moderate atmospheric moisture to prevent injury to the foliage. Fertilise each bunch

leaving nothing to chance, and if there be a deficiency of pollen employ Hamburgh pollen, and reduce the strain on the Vines by removing any surplus ill-shaped bunches, a temperature of 70° not being too high on mild nights, but on cold nights 5° less will be safe and even beneficial. It is advisable to admit a little air constantly whilst the Vines are in bloom.

Succession Houses.—Let all stopping, tying, and regulating the young shoots be done after the sun has been shining some time on the house, as they are then limp and less liable to snap. Thinning is best performed in the morning or evening, and in no case ought the berries to be handled. Maintain a good moisture by damping available surfaces in the morning and in the afternoon at closing time, sprinkling the paths before nightfall with weak liquid manure. Allow the laterals to extend as far as space admits, but avoid crowding either the principal or lateral growths.

Late Houses.—Make the most of solar heat for pushing on Vines of Lady Downe's and other late-keeping sorts, as all the thick-skinned varieties cannot be over-ripened if they are to be kept in good condition for months after they are cut from the Vines. Admit air early on fine mornings, the neglect of which is the most prolific source of Vine and other foliage being scorched, allowing the temperature to rise to 80°, having a good amount of moisture in the house for the benefit of the tender foliage, and close sufficiently early to cause the temperature to rise to 90° from sun heat on bright afternoons, allowing it to fall to 60° at night, which will be quite sufficient until the Grapes come into flower, when a temperature of 65° at night and 70° to 75° by day by artificial means must be secured to them to increase the size of the bunches, and provide conditions favourable to setting. Leave nothing in the setting of late Grapes to chance, but resort to artificial impregnation. A camel's-hair brush drawn over the bunches when the pollen is ripe will set matters right even with most shy setters, as it will remove the glutinous drops or substance that adheres to the stigmas, which undisturbed prevents the berries from setting, and removed enables the berries to be set quite as well as the freest setters.

Melons.—The earliest plants are ripening their fruit, and must not be damped, as that would cause the fruit to crack. A moderate moisture, however, in the atmosphere will be necessary for the foliage. If it be considered advisable to take a second crop from the same plants, and although a rather dry, somewhat high and airy atmosphere is favourable to ripening and flavour, it must not be overlooked that the healthier the plants are at the time the fruit ripens the more highly finished it will be. When the plants are in a clean healthy condition they will show and set a second crop of fruit after the first has attained to its maximum size, and these will be swelling, and must not be allowed to suffer by want of moisture at the roots of the plants, which will not injure the ripening fruit in the least, as the young swelling fruit will appropriate the nutriment and prevent the liability of the ripening fruit to crack when there is no swelling fruit to take the food. When the ripe fruit has been cut loosen the surface of the bed with a handfork, not damaging the roots, and add a little fresh soil, treading or pressing it down, and give a good watering with tepid water, and afterwards with liquid manure. Thin, stop, and regulate the growths, avoiding overcrowding as the greatest of evils, and remove bad leaves and exhausted growths. Damp the paths, &c., before night with liquid manure as a stimulant and preventive of red spider, and syringe where the fruit is swelling in the morning and early afternoon, closing in good time. Ventilate early in the day, keep the house through the day at 80° to 85° or 90°, and allow the temperature to fall to between 65° and 70° through the night by morning.

Plants in succession houses, pits, and frames will require attention almost daily in stopping, tying, and thinning the shoots. Impregnate the blossom about the middle of the day, when the pollen is dry, performing the operation at the same time in order to secure a regular set, so that the fruit may swell together and be distributed over the principal shoots as evenly as practicable, stopping each lateral one joint beyond the fruit. Earth up the roots as soon as the fruits are fairly swelling, and supply liquid manure after the roots become active in the fresh soil, maintaining a good moisture by syringing on fine afternoons and closing early. Remove all blossoms, and keep laterals closely pinched to one joint. Shade only to prevent flagging, and ventilate early to prevent scorching.

Houses that have been used for winter Cucumbers or early Vines in pots may be utilised for Melons. Wash the woodwork with soap and water, the glass with water, and the walls with quicklime. Remove every particle of soil from the beds; make up fresh ones of sweetened dung and leaves if bottom heat be furnished by that means, or if rubble is placed around and over hot-water pipes see that it is free, so as to insure perfect drainage, and secure with a layer of turves grass side downwards. Form ridges or hillocks of good turfy strong loam with an admixture of a tenth of old mortar rubbish, and if deficient of grit add a similar proportion of road scrapings. A tenth of charcoal broken rather small will be advantageous if the soil is full of vegetable matter—i.e., decaying fibre. Press the soil firm, and when warmed through plant out, making the soil firm around each. Sow for succession, and prepare plants for putting out in pits and frames after Potatoes.

Cucumbers.—In order to maintain a regular supply of fruit, stopping, thinning, and regulating the growths must be regularly attended to, not allowing it to become overcrowded, but by the removal of superfluous and exhausted growths keep up a succession of bearing wood, avoiding over-cropping, and maintain a good surface root-action by surface dressing occasionally with light loam and a fourth of well-decayed manure added. Water with tepid liquid manure when needed, which will vary with the circumstances under which the plants are grown. Those in pots or boxes will need it daily, and those in beds over hot-water pipes will need it

much more frequently than those in beds over fermenting materials, the former requiring it every other day, whilst the latter will not require watering oftener than once or twice a week. Syringe twice a day during bright weather, damping available surfaces only in dull. Admit air freely in mild weather, but do so carefully in cold weather, and keep the air charged with ammonia vapour by sprinkling the floor, in the evening. See that dung-heated beds are not allowed to become cold from inattention to the linings, and as yet continue night coverings.

PLANT HOUSES.

Allamandas.—The earliest plants are growing rapidly and require more water at their roots. If trained under the roof keep their shoots tied to the wires, but those upon trellises should not be tied closely until they are showing flowers freely. Grow these plants at this season of the year in full sunshine, or their growths will be very long before they show flower. Keep a sharp look-out for yellow thrips, which is destructive to the points of the shoots, a moist atmosphere and liberal syringing are the best preventives. If they become established fumigate or dip the shoots in tobacco water. Those plants intended for flowering late in the winter and have been at rest may be pruned, potted, and started gently.

Stephanotis floribunda.—Plants started early in the season will now be growing vigorously, and should not be kept in too close an atmosphere. They should be in a light position and fully exposed to the sun, and need a somewhat drier atmosphere than many stove plants if they are to flower profusely. The shoots as they extend, whether trained upon trellises or otherwise, should be trained close under the roof of the house in which they are growing. Thin cord is the best to train the shoots to, as it can be cut and the plant taken down more quickly than if trained to wires. Shorter growths are produced, but the plants flower best when grown in an intermediate temperature.

Gardenias.—Blossoms are now unfolding in abundance if they have been forwarded in brisk heat. If the supply is too numerous move those in the most backward condition to a lower temperature, which will prolong their season. Plants that have been brought forward gradually since their buds were set will be found invaluable when the early batches are past. Those that have flowered may be pruned hard back and started in brisk heat unless young stock was propagated in autumn. When blossoms are required early do not prune them, except to remove straggling shoots, but grow and ripen them in a cool house early and then start them in brisk heat. Attend to stopping the shoots of young plants in 5 and 6-inch pots, and repot those rooted some time ago. These if attended to and liberally treated will make grand plants for flowering about this time next year.

Grevillea robusta.—The seed sown as advised has germinated, and the seedlings are ready for placing in 2-inch pots. If the plants are wanted quickly push them forward in brisk heat; if not, allow them to become established after pruning, and then grow them for a time in an intermediate temperature, and finally under cool treatment. A strong plant or two should be grown from year to year for supplying foliage for cutting, which is equally as beautiful as Fern fronds and lasts much longer. Another batch of seed should be sown, which, if not soaked previous to sowing, will take fully three weeks before it germinates. The seed should be well covered with soil of a light nature. Employ for a compost good loam, with a seventh of manure and sand.

Cinerarias.—The earliest seedlings will be ready for pricking-out from the seed pan into others about 1 inch apart. Gradually remove them from the heat in which they have been raised to cooler quarters, for if drawn up weakly in heat they seldom make specimens of the most satisfactory condition. Sow a little more seed in an intermediate temperature; the dwarf and compact strains are more useful for decoration than taller forms.

Primulas.—Prick out the plants singly as soon as they are large enough in shallow pans about the same distance apart as Cinerarias, and from these pans they will be large enough for small pots. Fill the pans with a compost of half loam broken fine, leaf mould, and a little sand. Keep them on a shelf close to the glass in a temperature of 60°, and shade from strong sun. Another pinch of seed may be sown. Keep plants of good varieties intended to seed upon a shelf where the atmosphere is moderately dry and the temperature 50°. If the flowers are fertilised on a fine bright day with the aid of a small camel's-hair brush the plants will seed freely, which is not generally the case if left to chance.

Balsams.—These are useful for conservatory decoration, and can either be grown into large specimens quickly or flowered in a small state, whichever is most convenient to the cultivator. The seedlings should be potted as soon as they are large enough into 3-inch pots as deeply in the soil as possible; in fact, the two seed leaves only should be above the surface. After potting water and place them upon a shelf close to the glass in a temperature of 60°. As soon as they are established they must have air daily, or they will draw up weakly. Some strains need pinching to make them branch freely, while others branch naturally. Repot directly they require it if large plants are desired, for they should never suffer from insufficient root room until they are in the pots they are intended to flower in. Some useful decorative plants can be grown in 6-inch pots, but they must be liberally fed when their pots are full of roots. They succeed best if plunged in a hotbed where the top heat is not too high. A little seed for succession may be sown every month. Use for a compost good loam, leaf mould, manure, and sand.

Coleuses.—These are useful for the conservatory and decoration during the summer. They should now be propagated and grown for the purpose. If large plants are required pinch their points out as soon as

rooted and pot them in any light rich compost. The only attention they need is heat, water, and attention to stopping and tying out the shoots to form the base of the specimen. They must be grown fully exposed to the sun, or they will be deficient in colour. No plants look better or are more conspicuous than these when grown strongly in small pots. We grow quantities without being stopped, while others are only stopped once and allowed to form about four shoots, which are more effective amongst flowering plants than those of a larger size.

Fuchsias.—Pot these as they require it, whether large or young plants. Attention should be paid to pinching the shoots and removing the flowers as they appear until the plants are well furnished, when they may be allowed to flower. Young plants just placed in 6-inch pots should be kept as close to the glass as possible. Keep them in a night temperature of 55° to 60°, and give air freely during the day to ensure a sturdy growth without being stopped. If properly treated they should when from 14 to 18 inches high be perfect little pyramids. If bushes are wanted they must be stopped until they are large enough and allowed to flower. Syringe liberally, and water freely when in active growth.

THE FLOWER GARDEN AND PLEASURE GROUND.

Lawns.—The mowing machine has already been set to work on many lawns. If the grass is kept rather closely cut now the cutting will be more lightly and more neatly performed throughout the remainder of the season. The edges will also require attention, and should be heavily beaten down or rolled before being cut with the edging iron, otherwise the walk will be gradually widened, but not improved at the expense of the turf. Never attempt to cut the turf edges without a line properly pegged into position, as by no other means can the work be done neatly. For the rest of the season the weekly use of edging shears is necessary for keeping edges neat. Large weeds on the lawns, such as Dandelions, Thistles, and Plantain, spoil its appearance, and cutting out only serves to further spread them. They must either be drawn out with tap root entire or be destroyed with oil of vitriol. This acid should be kept in a strong bottle, and applied with a stick pointed and notched. One drop on the heart of each weed is generally sufficient to burn them up. Daisies may be cut out with an old knife, and moss kept down by frequent stirrings with an iron rake as well as a dressing of road grit and wood ashes.

Walks.—Where there are but few weeds upon the walks they are best handweeded, but where they are very green they may be destroyed with coarse common salt applied during dry hot weather, enough being given to whiten the surface. Boiling water freely applied through a rose watering pot on a sunny day will do much towards clearing walks and pavements of weeds, and the remedy will be more effective and lasting by adding powdered arsenic at the rate of 1 lb. to twelve gallons of water. As the arsenic is a strong poison it should not be used where fowls or game have access to the walks, or they may be poisoned with the grit they pick up. Soda boiled in water at the rate of 3 lbs. to six gallons of water is also very destructive to weeds. Crude carbolic acid at the rate of 1 oz. per gallon of cold water and carefully distributed over the walks is perhaps the simplest and best remedy of all for both weeds and mosses. Whatever is used, care must be taken to ward it off with sloping boards from both the tops and roots of the Box edgings as well as the turf. Newly gravelled paths should be rolled occasionally; some gravels binding best when wet, while others are picked up if rolled during showery weather. The latter are unsuitable for walks, and should be faced with either ground or crushed spar, or good binding gravel procured from another district. For the back paths clinkers roughly broken, covered with some of the roughest ashes and faced with that sifted, if well watered and rolled, binds well, and the path will be clean and good for three or more years, according to the traffic. All walks should be well rounded and provision made to carry the water away without its disturbing the gravel.

Sowing Annuals.—In warm gardens where the soil is light and good, and where also slugs are not very troublesome, many kinds of annuals may now be sown. These may include Mignonette, Candytufts, pot Marigolds, Eschscholtzias, Collinsias, Coreopsis, Cornflowers, Clarkias, Godetias, Convolvulus major and minor, Lupins, Larkspurs, Linums, Nemophila, ornamental Grasses, Silenes, Saponaria, Virginian Stocks, Love-lies-Bleeding, Scabious, Nasturtiums [Tropæolums], Poppies, Hibiscus, Gaillardias, Asters, of which the best are the Victoria and Truffaut's Pæony-flowered; Stocks, the most serviceable of which are the Earliest-flowering Autumn; Helichrysums, Zinnias, Dianthus, and Phlox Drummondii. Sow thinly in patches and according to their respective heights, cover with a little sifted sandy soil, and mark each patch with a peg. On colder soils the choicer sorts, especially the last six mentioned, should either be sown in boxes or frames and be transplanted. In our case, owing to the abundance of slugs, the majority have to be sown under glass, the exceptions being Eschscholtzias, Poppies, Love-lies-Bleeding, and Nemophila, these transplanting badly, and extra trouble has to be taken with them where they are sown in the open.

Gladioli.—The principal portion of these ought now to be planted, one or two more plantings being made in order to afford a succession of bloom. A rather light sandy soil best suits them, but the commoner *Brenchleyensis* type will grow in almost any kind of soil. The ground should be dug deeply, some good rotten manure being worked into the bottom of the spit. Surround the corms or bulbs with sand and cover with about 2 inches of good soil. For affording serviceable spikes of bloom the old lilac *G. Colvillei* and the choicer *G. Colvillei alba* are recommended, and room may well be found for them in every herbaceous or mixed border.

Violets.—The hardy varieties of the Czar type require to be frequently replanted, or otherwise they become a mass of leaves, in which state but few good flowering crowns are formed. On strong soils they ought not to remain undisturbed for more than two seasons; but on light soils where a difficulty is experienced in getting them to do well, they should only be thinned out and mulched with partially decayed manure. Before making a fresh plantation on light soils add a good dressing of clayey loam, as they invariably succeed best on firm rather heavy land, such as suits Strawberries, and may well be grown in similar positions. Dig deeply, divide the old plants into small pieces with a few roots attached, and dibble them in firmly about 15 inches apart each way. On light soils a mulching of manure to be given at once, and the retention of the moisture will serve to ward off the attacks of red spider, which sometimes greatly damage the foliage of Violets. A sprinkling of salt will benefit the older beds, and the clumps where at all crowded should be freely reduced. Among the doubles Marie Louise is the most popular, but is not perfectly hardy. The runners make the best plants, and if these can be taken off with roots attached they may be planted 1 foot apart in good soil, and in the autumn be transplanted to frames or where they can be protected with handlights or frames. The runners not rooted may be dibbled round the sides of pots, kept in a close frame till rooted, and eventually planted out. The old plants will also divide equally as well as the single sorts.

THE BEE-KEEPER.

EXPERIENCE IN BEE-KEEPING.

WOULD it be worth while giving your readers my short experience in bee-keeping? perhaps it would. My original outlay was as follows :—

						£	s.	d.
November, 1882.	A stock in straw skep	0	12	6
" " B "	" " "	0	10	0
" " C "	" " "	1	0	0
One bar hive and sectional super	" "	0	12	6
One bar hive (made myself)	0	5	0
Common straw skeps	0	5	0
Glass supers I had in stock	0	0	0
Total original outlay	£3	5	0

And now to give summary of results:—

								£	s.	d.
A gave 4 lbs. of super honey and no swarm	0	5	0
B died early in December, owing to paucity of bees	0	0	0
C gave two swarms, D and E	0	0	0
D gave 10 lbs. of finest super honey	0	12	6
E gave 7 lbs. of inferior honey from body box	0	7	0
								<hr/>		
Results	£1	4	6
Expenditure	£3	5	0
Returns	1	4	6
								<hr/>		
								£2	0	6

Remainder of original outlay to be wiped off £2 0s. 6d., and against it must be set A, C, and D. E was united. A is very strong; on Sunday last I counted over 100 bees a minute coming in. C is very strong; on same date I counted over 70 bees a minute coming in. D over 120 per minute coming in. They may surely be valued at £1 each, against which must be set 5s. for feeding the three—£2 15s. In reality they are "here" worth more. My state now is then:—

Remainder of original outlay..	£2	0	6
Value of stocks	2	15
								0
								0
								6

I have also an empty bar hive and three combs on hiving skeps which I will not value at anything, but set them against the fact that I had not to buy glass supers. I began to feed on the 23rd February in the case of A and D, and later in the case of C (about the 15th March). With my first year and my prospects for the coming year I am well satisfied. If anyone by reading this summary of receipts and expenditure is induced to become one of the ever-increasing few bee-keepers the trouble in preparing it will have been but a pleasure, and the thought of the many happy hours a novice will enjoy in watching these most interesting of insects will be a spur to many to give their varied experience. For myself I am prepared for "bad years," "failures," and "losses," and so must all be; but I rest assured that the reverse will so often be the case that they will soon be forgotten amid years of plenty.—T. M.

CYPRIAN AND SYRIAN BEES.

THE Ligurians have been rather severely criticised lately, and I have waited to see the Cyprians and Syrians placed in the same black list, or blamed for many of the bad qualities imputed to the Ligurians; but "Hallamshire" having written in their praise, or rather in the praise of Syrians, I write to warn those who are disgusted with Ligurians from taking up Cyprians and Syrians in their stead, as they possess all their faults with none of their virtues. Our cousins across the Atlantic seem

to think very highly of them, and are trying by selection and cross-breeding to get a gigantic gold-coloured bee, for which they have already found a name, *Apis americana* I think it is. Meanwhile they are using their fertile minds, with pretty good success, to make wax, comb, and honey without the help of bees in any way.

An enterprising friend of mine took the trouble to import a large number of these Cyprians and Syrians, and there were about thirty stocks distributed within an area of a few miles of where I write; in fact, I know who owned most of them, and we are now all agreed that they are quite unsuitable for this climate. To handle them with smoke is impossible. They can only be manipulated slowly and carefully, and we feel all the while at their mercy. I have had a few lively times with bees in my 'prenticeship, but five minutes I once spent with a stock of Cyprians is still fresh in my memory. They not only used their stings, but bit as well. They brought with them some of the finest specimens of wax-moth grubs I ever saw, besides other vermin. They are incessant workers, early and late; a Scotch mist will not keep them at home. They breed rapidly, wear out their queen, dispatch her, and rear others with little consideration, and when blacks are storing they are consuming all their income on brood.

In the summer of 1882 I supered a very strong stock at the same time as I did six stocks of natives. There was a glut of Clover and Bean honey, and a bee-keeper friend calling to see me I showed him my supers being rapidly filled by the blacks, but when we came to the other I well remember the comical expression of his face as he remarked, "You did not expect them to fill it? None of mine have. I guarantee you will not find a pound of sealed store in the stock hive!" And this we found was the case, although it was crammed from end to end with brood. Later on they stored, but at whose expense? Having no Heather in this neighbourhood we do not get honey gluts in October. The result was that winter came and they were unprepared, and the following spring the majority of these thirty stocks were destroyed with dysentery, and the neighbourhood has been tainted with foul brood ever since. My friend the importer kept clear of the scourge, and, fortunately, so I have myself, but I know the amount of vigilance it cost him, and we have cleared out the foreigners from our apiaries.

Let us improve anything we can by all means, but let us admit the uselessness of puffing anything that is but a mere fad. Foreign bees are so mixed now, the Cyprians and Syrians having been introduced into the Italian breeding apiaries to improve the colour of the Ligurians, and even English black queens have been introduced to maintain their physique, and all to satisfy this insatiable craze for novelty so dear to the heart of Englishmen.

In justice to the British Bee-keepers' Association I must say they are doing their best to improve the use of the straw skep in the hands of the inexperienced cottager, and rightly, too, in my opinion; for after all the great aim of bee-keeping is to fill the honey pot, and not to give us gold-coloured bees as large as hornets to ornament our gardens as they pass from flower to flower.—J. P. S.

TRADE CATALOGUES RECEIVED.

James Cocker & Sons, Aberdeen.—*Catalogue of Florists' Flowers for 1884.*
Thomas Painter, Smallwood, Stoke-on-Trent.—*Catalogue of Dahlias.*
Bruant, Boulevard Saint Cyprien, Poitiers, Vienne, France.—*Catalogue of Plants for 1884.*
Louis de Smet, Ledeborg-lez-Gand, Belgium.—*Catalogue of Plants for 1884.*
William Bull, King's Road, Chelsea.—*List of New and Beautiful Plants.*

* * All correspondence should be directed either to "THE EDITOR" or to "THE PUBLISHER." Letters addressed to Dr. Hogg or members of the staff often remain unopened unavoidably. We request that no one will write privately to any of our correspondents, as doing so subjects them to unjustifiable trouble and expense.

Correspondents should not mix up on the same sheet questions relating to Gardening and those on Bee subjects, and should never send more than two or three questions at once. All articles intended for insertion should be written on one side of the paper only. We cannot reply to questions through the post, and we do not undertake to return rejected communications.

Books (A. H. P.).—Brown's "Forester" (Blackwood) is the only full and practical work that we can recommend as likely to meet your requirements. London's "Encyclopædia of Trees and Shrubs" (Longmans) you would also probably find useful as a work of reference. Other works, so far as we know, are merely compilations from the above, nor are we aware that any original work is in preparation on forestry and arboriculture. The publisher can

supply you with vols. ii. iii. and v. of the new series, but not vol. iv. We do not know of any other way of obtaining this than by advertising.

Errata.—At page 291, under the paragraph "*Rhododendron Veitchianum*," "nearly two blooms" should read "nearly two hundred blooms," and for "roots" small "shoots."

Destroying Weeds on Walks (Eight-years Subscriber).—Perhaps you allude to destroying them with carbolic acid, of which you will find particulars in our "Work for the Week" of the present issue. The water is first placed in a garden can with a fine rose, the acid measured and poured into it. No stirring or further mixing is requisite, but it is immediately poured over the weeds through the rose, care being taken to make the entire surface of the path wet in order to destroy the weeds. Care must be taken not to let the acid touch the hands, clothes, or boots. You had better not use the acid for destroying weeds on land that has to be afterwards cropped, as sufficient to kill the weeds would also prevent the growth of the crops you might desire to cultivate.

Muscat Troveron Grape (A Sussex Grower).—If you have been led to expect that this Grape would even approach in appearance the Muscat of Alexandria we are not surprised at your disappointment. It is totally distinct from the oval-shaped Muscat Grapes, and is not classed amongst them. It is a Frontignan Grape, its proper name being *Troveron Frontignan*. The berries are round, of good size for a Frontignan, but small as compared with the true Muscats. The colour is amber, but often tinged with a reddish brown colour, which gives the fruit a rusty appearance. The flesh is firm and crackling, and the flavour excellent, with a strong Muscat aroma. Those who covet a number of varieties of Grapes, or who desire Grapes of high quality regardless of appearance, may grow the variety in question as one of the best of the Frontignans, but it cannot be compared with the Muscat of Alexandria for producing handsome bunches and berries of first-class quality. The *Troveron Frontignan* is a good grower, and in all probability a Muscat inarched on it would succeed. We should try it in preference to uprooting young and healthy Vines.

Climbing Plants for Vinery Wall (Reader).—One of the best plants for this purpose is *Heliotrope*, which yields a supply of fragrant flowers throughout the greater portion of the year, and is therefore extremely useful. *Hoya carnosa* also grows very well in such a situation, and some Roses, especially *Maréchal Niel* and *Gloire de Dijon*, succeed and flower readily. *Bougainvillea glabra* may be grown if more are required, but will require great care in keeping the plant free from mealy bug. Camellias are excellent for covering shaded walls.

Propagating *Daphne indica* (Idem).—We presume that the *Daphnes* you have are *D. indica* or its varieties, all of which may be propagated by cuttings of the young wood inserted now in sandy soil in a warm frame. They are also grafted in stocks of *D. Laureola* raised from seed, shoots of the former 2 to 3 inches long being selected and splice-grafted to the stocks, which need not be headed down until after the union is completed. They should be placed in a propagating pit or heated frame, and carefully watered.

Maréchal Niel Rose Cankered (G. F. M.).—We are glad that our reply has enabled you to discover the cause of the plant's debility. As the canker is so low you may possibly restore the lost vigour of the tree. Clear away all the old soil, and well wash the cankered part, dusting it with sand and crushed charcoal, then pack round it and for 6 inches above the injured part some turfy loam mixed with decomposed manure and charred refuse, and if this is kept regularly moist, without being saturated so as to render the compost sour, young roots will probably issue from the healthy portion, and give to the Rose a new lease of life. We have seen this method of renovating *Maréchal Niel* practised with great success. The grubs you have sent are the larvae of the Daddy-longlegs (*Tipula oleracea*). They are very destructive, and most difficult to eradicate. Starlings are their natural enemies, and a mixture of soapsuds and petroleum or a solution of hellebore are the most likely applications to destroy them.

Beetle Injurious to Peach (Anxious Inquirer).—The insect forwarded is the clay-coloured weevil (*Otiorhynchus picipes*), apt to be troublesome in the spring to a variety of fruit trees, especially those against or near walls. Whether the mature beetle always hibernates is uncertain, but it is probable that the habit of the species is to hide under the earth through the winter months or in cracks and crannies about walls, hence the importance of keeping these clean and well pointed. Where it is suspected these weevils have made a lodgment it would probably be beneficial to apply to the walls a mixture of sulphur and soft soap, 1 lb. of the one and 2 ozs. of the other to each gallon of water might be suitable, the compound being thickened with clay so as to form a paste. After the weevils have come forth (if previously undetected) they may be hand-picked, as you suggest, or shaken from the shoots into cloths placed beneath.

Vines Failing (W. M. M.).—The specimens you have sent have been subjected to microscopical examination. They are not affected by either insects or fungus, but the epidermis is withered and the sap vessels ruptured. The growth is destitute of vigour, but whether the fault is in the horder or not we have no means of knowing. We feel pretty certain, however, that the house has been kept too close and moist, and especially that the ventilation has not been attended to sufficiently early in the morning, and then when the lights have been opened they have been opened too widely. The result of this is excessive evaporation from the foliage, which causes a chill, the effect of which is usually known as "scorching." The fault is not in the Vines that were purchased, for better are not obtainable than from the source you name, but in the treatment to which they have been subjected. Is the border sufficiently moist, not on the surface merely, but quite through the mass of soil? A dry border, moist atmosphere, and low temperature at night, with late and excessive ventilation in the morning, would have just the effect exhibited by the laterals before us. There is no cure for the parts already decayed, but by according the treatment suggested the Vines ought to be in a much better condition another year.

Insects in Manure (E. A.).—They may be destroyed in the manure and anywhere else where there are no plants by applications of boiling water. This, of course, must not be applied to the Mushroom bed. Perhaps the best method of destroying the insects there would be to mix about 2 czs. of salt

in a gallon of water, and apply this to the beds. It may possibly destroy the insects and induce the growth of Mushrooms. It must not be given to plants in pots, nor to seedlings in boxes. We doubt very much if the insects are the cause of the seedlings disappearing. The evil is more likely to be the result of some defect in ventilation or watering, or both.

Amaryllis aulica (*Miss Milward*).—The above is the name of the species of which you have sent a flower, and we are glad to hear of your success in cultivating it. It is very free and useful, and has contributed markedly in imparting vigour to the much grander varieties that are now being established.

Hellebore Powder and Caterpillars (*H. M. S.*).—The trees are syringed, one person carefully holding up the branches, so that all the parts are made wet, then the powder is applied through a dredger like a pepper-box, but with larger apertures through which it can pass freely; it then adheres to the leaves and caterpillars, and does not leave many of the latter alive. The hellebore can be mixed with water and applied in the form of "tea" with the syringe. Its use is not recommended when the fruit is advancing to a size ready for gathering. Waldsteinias can be obtained from nurserymen who advertise hardy flowers in our columns. It is contrary to our rule to recommend dealers, on the ground that it would be most unfair to do so.

Cutting down Dracæna Draco (*G. S.*).—The wood is probably too hard towards the lower portion of the stem for it to produce roots, but if you partially cut it nearer the top, say a foot or two below the leaves, you will no doubt be more successful. The moss placed round the stem must be kept constantly moist for several weeks, but in the event of that failing your only course is to cut the upper part off as suggested, though the experiment will be a hazardous one. The position you name would be a suitable one, and if there was any chance of success it would be attained by placing the stem in the bed of cocoa-nut fibre refuse.

Fungus in Vinery (*S. E.*).—We are very glad to hear that our advice has proved so useful to you. The Vines, judging by the samples before us, have certainly improved wonderfully. So long as they make free progress we should refrain from closing the house in the afternoon with much moisture, but we should be content with damping it occasionally and maintaining a genial and buoyant atmosphere. The Vines will probably recover without the ammoniacal liquor; at least we think you may venture to try them.

Hardy Carnations and Picotees (*S. H.*).—The following varieties will probably suit your purpose. Carnations and Picotees are naturally later in blooming in the north than the south irrespective of varieties. We name one variety in each class. *Carnations*: Admiral Curzon, scarlet bizarre; Rifleman, crimson bizarre; Falconbridge, pink and purple bizarre; James Douglas, purple flake; Clipper, scarlet flake; John Keet, rose flake. *Picotees*: J. B. Bryant, heavy red edge; Mrs. Bower, light red; Mrs. A. Chancellor, heavy purple; Her Majesty, light purple; Mrs. Payne, heavy rose; Mrs. Allcroft, light rose.

Names of Plants (*H. K.*).—A variety of *Odontoglossum Wilckeanum*. (*Constant Reader*).—1, *Aucuba japonica* (male plant); 2, *Lonkera tatarica*; 3, *Primula cortusoides*. (*W. S.*).—The blue flower is *Charlieis heterophylla*, the other is *Eupatorium riparium*. (*S. S.*).—1, *Chorozema ilicifolia*; 2, *Monochaetum sericeum*; 3, *Alonsoa incisa*; 4, *Diosma ericoides*; 5, *Forstythia viridissima*; 6, *Agathæa cœlestis*. (*W. M., Brockley*).—*Caltha palustris*. (*J. H.*).—The red flower is *Echeveria retusa*, the white one *Eupatorium riparium*, and the other is *Russelia juncea*. (*Somerset*).—Ferns.—1, Resembles a variety of *Nephrodium molle*; 2, *Pteris longifolia*.

COVENT GARDEN MARKET.—APRIL 16TH

ALL branches of the trade dull, with good supplies, Strawberries especially meeting with little demand. Prices without alteration.

departure whereby the dairymen may increase their produce, improve and regulate the supply, with advantage to themselves and the satisfaction of the consumers. Some facts in connection with the popular mode of treatment of their cows by the dairy farmers are so generally adopted by pursuing an old system as to amount to a prejudice, although it is equally injurious to themselves and the consumers of fresh butter; for any system which prevents the farmer from obtaining full commercial profits, and at the same time diminishes the supply of his products to the consumers, must be discredited by every sensible and practical farmer. Notwithstanding these facts, they are entirely unheeded by the majority of the dairy farmers; and the consumers, particularly in the winter months, are thrown back upon a supply from abroad which is commonly called "Bosh," and for some time was sold as salt butter. Although we have "adulteration Acts," which were ostensibly enacted for the purpose of securing the consumers against imposition, it has been found that the Acts are so worded as not to protect the consumers so long as it is not sold as butter, and could be by analysis shown not to be injurious to health.

It is notorious that large factories in America exist for the manufacture of oleo-margarine, which is now an article of commerce sold to almost every nation that furnishes the imports which supply the consumers of this country; and it is also stated that in some dairy districts where the cows are let for the season to dairymen who manufacture fresh butter for sale, that since the introduction of oleo-margarine, where there is no restriction to the contrary, the article is used, and the cows are let at £2 sterling more money per head per annum than at any previous time before this article came into use. This fact points to the idea that dairymen who rent their cows make use of this material for the purpose of adding to their produce of butter, even during the summer, and thus the quality of the article, although increased in supply, is greatly deteriorated. In most cases, however, it does not answer a good purpose, and if it has not succeeded in the past how is it possible that it can prove beneficial in the future to the consumers or those engaged in producing butter for sale either abroad or in this country? Much has been revealed lately upon this subject; but the following, which appeared in the *Standard* newspaper of March 24th last is very remarkable:—

"A Committee of the New York Senate has reported the results of an inquiry into the adulteration of dairy products. The details are disgusting and alarming. Of thirty samples of butter two-thirds were only remotely traceable to milk. The refuse fat of pigs and bullocks was the chief and most savoury ingredient; but often spoiled greases were used which had been deodorised by nitric and sulphuric acids of a strength sufficient to induce lingering diseases. The material was also found to contain ingredients which are fatal to infants. The doctors, upon oath, declared that the consumption of this compound had a distinct bearing upon the death rate. The Committee advises the total prohibition of the manufacture of oleo-margarine. The interest in this subject is not merely local, as the exports in February included nearly a million pounds of butter, and over three millions of cheese."

We forbear dwelling on the effects likely to arise from a statement which speaks for itself, and proceed to consider the best mode of improving and regulating the supply of home-made fresh butter. Fresh butter may be improved in various ways; but more especially by careful feeding with suitable materials at the best time and with judicious allowances, but also with pure fresh water available at all times, whether the cows are housed or feeding in the pastures. This refers to the feeding in summer time; but it should be remembered that in the case of a short supply of grass in the pastures supplementary food should be given twice a day, both of green fodder crops and crushed Oats or Wheat (of each 3 or 4 lbs.), given at each milking time in these moderate quantities. In feeding during the winter months it is necessary to consider the opportunities available for obtaining food of our choice. For instance, we are satisfied that as to the experiments relating to ensilage, especially that obtained from the best field Grasses and Clovers; but that made from Maize being the most valuable of all, especially for butter-making, though the crushed Oats or Wheat must not be omitted, for the firmest and best quality butter will be obtained from the feeding with Oats or Wheat. Still, as ensilage is by no means available for all dairy farmers it is important to consider the next best foods for use in the absence of pasture grass, and that which we find to be best is pasture hay well secured, with Potatoes of the large cattle-feeding varieties passed through Gardner's cutter and mixed with crushed Oats and Wheat, with some malt dust. In the absence

IMPROVING AND REGULATING THE SUPPLY OF FRESH BUTTER.

It will be found in considering this subject that both the dairy farmers and consumers are greatly interested in a new

of Potatoes, Mangolds, Carrots, Cabbages of the large Drumhead Savoy sorts may be given; but whenever roots are given when feeding a butter-making cow it will be necessary to avoid or diminish any unpleasant taste arising from root-feeding (except Potatoes) to give them immediately after the cow is milked instead of at milking time. These observations, of course, apply especially to the quantity of milk, because if we have made a selection of the right cows as to breed, we shall find that the more milk obtained the more butter will be produced after feeding as above recommended.

Referring to the breed of cows for the purpose of furnishing butter of the best quality, we cannot recommend any which has furnished so large a record of choice butter as the Guernseys, both in this country and in America. We once had a Guernsey cow, and whilst getting only good pasture grass, she made for several weeks in the month of June 18 lbs. per week of butter of the best quality and deep yellow colour. It is also recorded that a celebrated cow named "Elegante," of the pure Guernsey blood, and owned by Mr. L. W. Ledyard of Fernwood Farm, Cazenovia, New York, and which was capitally portrayed in the *Agricultural Gazette*, and also in this Journal on Nov. 8th, 1883, produced 19½ lbs. of butter per week; but it must be remembered as a fact of the highest importance in relation to the butter record, that in both these instances there is no doubt but that three milking daily instead of twice only would have produced a higher record than as above stated. Another point is, that where the highest record is to be attempted, the feeding generally should consist of a full quantity of the best known materials; yet, although we may have obtained butter of the best colour, aroma, and taste, firmness is also a consideration. Our chief reason for recommending the feeding with crushed Oats, Wheat, and malt dust, is to secure that firmness and quality in butter which is only or seldom attained by a system of feeding when these materials are absent.

In maintaining high records of the best butter for the longest possible period, the ordinary rules of management, if carried out with care will, with good feeding, prove sufficient; but notice should always be taken whether the cow drops her milk from the udder between the usual hours of milking, for if that occurs it will not only seriously injure the cow in the future, but also render it impossible to obtain the highest record of butter, unless milking three instead of twice daily is resorted to. When milked three daily the udder must be quite emptied at each milking, for it must be remembered that the last portion, as taken from the udder, contains the most cream, whether milking is adopted twice or thrice in the twenty-four hours. Although we have recommended the pure Guernsey cow for butter-making, it applies chiefly to the small dairies where twelve or fifteen cows are kept, as in some suburban districts; for we still think that a first-cross animal, the produce of a good Shorthorn cow by a Guernsey bull, would prove the best in forming a herd of forty or fifty cows or more. Even in that case the cows may be of Guernseys only if required, but the herds should be formed into divisions of twenty each or thereabout, for half-breeds will generally bear herding in numbers much better than animals of the pure Channel Island breeds, whether of Guernseys or Jerseys, although the former are the stronger and hardier stock of the two, yet if abortion or any other accidental disease or difficulty occurs the disaster will be more easily dealt with.

(To be continued.)

WORK ON THE HOME FARM.

Horse Labour.—This is more required at this time of year than at some other periods, for there is not only the work to be done for the late seedings of Lent corn, but also at all available intervals after rain occurs, by working down any land which may have previously been too rough. The rains have, however, arrived just in time to save a large amount of horse labour both in harrowing and rolling on any fallow surfaces intended either for sowing with drege or Barley; but the importance of reducing the surface is the necessity of a fine seed bed to receive the Clovers and grass seeds of any variety. They are all small except Sainfoin seeds, and require to be covered shallow with fine loose soil, otherwise they may be buried too deeply or not at all. The horse labour, too, when it is driven away from the seedings as just named may be well employed on the fallows intended for root crops, some of which are usually at this time of year rough and ready for being broken down. Now is the time to prepare for Mangold seeding, the dung being first laid out and spread. Some farmers used to lay out manure on the fallow and plough it under in the early part of the winter. We have, however, to thank Sir J. B. Lawes for many savings in our farming business, and he has told us that fallowing in dung in the early part of the winter is liable to be diminished in value by some portion being washed out during the heavy rains of the winter and early months, and there is no doubt but much of the soluble and ammoniacal portions of the manure are lost, especially upon cold wet

soils. It is even a question whether yard dung, box, or stable manure should be applied at all to the early seedings for the Mangolds or early root crops. It frequently happens with this crop as with early Potatoes, whilst laying out dung the land may have been drilled and seeded in combination with artificial manures, and gain thereby in adverse seasons a good early seeding, when by laying out manure from the homestead the weather may change and the best seed time be lost. If full crops of ripe Mangolds are required the seed should be deposited in the month of April if possible. Some farmers, however, are afraid of the young plants being injured by frost; but in our experience, even from the first introduction of Mangolds as food for cattle, we have never seen any young plants injured by night frosts. There is a very general opinion prevailing that in the field cultivation for Carrots the seed should be sown in March at the latest; but that is not our experience, for the best Carrots and the greatest weight per acre we have ever grown were sown in the month of May, and frequently as late as the 20th day of that month for the best of all reasons, because it saves one hand-hoeing at the least; for if the seeds are deposited before the soil is warm enough for them to vegetate immediately, they do not come up until the weather and temperature become favourable. That is not the case with the weeds, for their seeds vegetate immediately, and before any hoeing can be done the young Carrot plants are completely hidden. We have seen this the case in some seasons when the weather has been rainy, so that the Carrots never could be hoed at all, the only exception being when the seed is drilled or dibbled on the stretch at 18 inches apart; the land can then be horse-hoed between the lines, and giving also an opportunity for effective hand-hoeing.

Hand Labour.—In numerous instances at the present time the sheep especially flocks of ewes and their lambs, are very lame in various districts with the foot-rot, as some farmers call it; but we call it the epidemic lameness, which frequently breaks out in consequence of its having prevailed ever since the year 1839, when it first broke out. It has since appeared whenever the season favoured it, because those animals which at breeding time have been mated were lame; it has therefore now and for many years become an hereditary disease, especially amongst the Hants and west country Down breeds, whereas long since we have been connected with sheep-breeding it was only the horned ewes and a few Downs kept on the same farms which ever had the foot-rot at all; but since 1839 all sorts and breeds have been subject to the lameness of an epidemic character more or less, and we see not the slightest probability of being entirely free of it again.

Live Stock.—Cattle are generally in good condition where free of foot, and-mouth disease, for the winter has proved one of the most favourable we can ever recollect, especially for dairy cows and young cattle. The bullocks in the boxes, too, where well fed, have done extremely well, as it is generally known and admitted that a mild winter with equable temperature is always favourable, inasmuch that warmth is considered equivalent to so much food. The early lambs bred from the best horned Somerset and Dorset ewes have sold well in consequence of the vegetable markets being well supplied with all accompaniments required where lamb is in season and forms a portion in the banquets of the wealthy classes. There is one thing which every practical farmer should take note of this season, that those who annually buy sheep for fattening in the winter months as a rule have made but little or no profit, whereas those who have kept a breeding flock will reap a considerable benefit.

OUR LETTER BOX.

Renovating Pasture (S. P.).—The present is a very good time for sowing grass seeds in your field, and the most practical advice we can give you is to state the present condition of the pasture, the nature of the soil, and the acreage to be renovated, to a seedsman or firm who pays special attention to this subject, and you may rely on receiving the right quantity of a suitable mixture for effecting your purpose.

REMARKS

6th.—Fair day, with some sunshine; wet evening.
7th.—Heavy rain till about 10 A.M.; dull morning; fine afternoon.
8th.—Fine all day, but rather dull afternoon.
9th.—Very fine all day; extremely bright moonlight night.
10th.—Bright pleasant day; very bright moonlight night.
11th.—Cloudy day; a little sunshine in afternoon.
12th.—Dull and hazy morning; drizzling rain in afternoon; clear cold night.
The middle of the week was very fine, warm, and bright, but the beginning and the end were unsettled. Temperature about three degrees below that of the preceding week, but still about four degrees above the average.—G. J. SYMONS.

AURICULAS—A REVIEW WITH REFLECTIONS.

AURICULAS are in the ascendant just now, and thousands of plants are sparkling with their lovely flowers. For chasteness in outline, perfection in character, and striking contrasts in colour, it is questionable if so much beauty is condensed into a similarly small space as in the flower under notice. It is quite true that all admirers of flowers cannot equally appreciate the charms of this pretty Alpine gem. We have heard a most extensive cultivator of hardy flowers describe the Auricula as "stilted, formal, and chilling," but that certainly does not represent the taste of the majority. There are still more individuals who cherish flowers, including Auriculas, but who are unable to comprehend the "points" of merit in a flower to which florists attach importance. We know that such is the case from the many seedlings that have been sent to us from time to time as possessing merit, but which were practically worthless as judged by the florists' high standard of excellence.

Most, if not all, the growers of repute have similar experience. On this subject the Rev. F. D. Horner wrote to us eight years ago:—"Some beginners (for one told me so) feel confused and lost as to what constitutes excellence, and even difference in the flower. One bemoaned the blindness through which he could see no distinction worth mentioning between a white and a grey edge. Well, there is more hope of him than of one fair visitor that day, who remarked that these Auriculas might be rare but they were not pretty! I do not know that these her words are worth embalming in the Journal, but it is well that tastes so charmingly differ. The sublimity of the Sunflower, the beauty of the broad Pæony, the brave spectacle of heavy masses of bloom, are the delight of many eyes; but without even affecting to despise these greater things, a florist with his flowers has that subtle enjoyment of his eyesight which delicate and curious flowers so well afford. May I, then, say to younger growers of Auriculas than myself, Do not be discouraged by present confusion and lack of discernment. You will feel and see your way as you go on. With an accustomed eye you will grow to detect a difference where now you see none. The differences that are so delicate grow to be quite plain. And this is one pleasure with Auriculas, that where the outside world that coldly wonders and passing on sees small variety, the eye of the florist finds many enjoyable and delicate degrees of beauty. I am sorry the Auricula is left languishing in metropolitan favour. One would have thought its bare claim as a spring flower would be enough to make it a great favourite everywhere."

With that we concurred. We regretted also that the flower was then "languishing" in the south; and hence it was that we readily gave such support and encouragement as was in our power to the effort that immediately followed in forming a southern branch of the National Auricula Society, which then only had one annual exhibition—namely, at Manchester.

When the southern section of the Society under notice, No. 200.—VOL. VIII., THIRD SERIES.

which has just held its seventh exhibition, was established, the whole question of special societies was very properly discussed in the horticultural press, and, rightly or wrongly, a verdict was arrived at that such societies have a tendency to degrade horticulture, and likely in the long run to do more harm than good. We were not able to assent to that dictum, and on the occasion of the first National Auricula Show being held in the Crystal Palace on April 24th, 1877, observed that such shows really promote horticulture in the most direct and practical manner. They take its departments in detail and perfect them the more quickly by a concentration of effort incident to their nature, and in the end do good and not harm. That first show was a great success, and we expressed a hope that it would be succeeded by others still greater, and that these beautiful flowers would increase in numbers and popularity. Greater shows followed, and the largest and the best of the series is reported in another column of our present issue.

Auriculas have also increased in numbers, and not a few very beautiful new varieties have been raised. Auricula growers are similarly more numerous, but there has not, perhaps, been a proportionate increase in the number of exhibitors of florists' flowers in the south. Though we should be glad if the number of exhibitors were tenfold greater than at present, we still see little to deplore in this absence of rapid increase. Exhibiting and making money by the process is not the object of all who grow flowers, only a mere fractional part of the community estimate their favourites by the amount they will win. Some possessors of small collections of plants hesitate to stage them in public from the conviction that they have only a very remote chance of competing successfully with the professional showmen, whose skill and resources they fear to encounter. Still it must be said that those who exhibit do so with no sordid object, but as an earnest of their desire to encourage others to become cultivators of flowers that afford such delight to the possessors. So earnest are many that they risk injuring their plants for the gratification of others, and from a financial point of view lose far more than they gain by their enterprise in exhibiting. Those are the true florists that are honoured and admired, and they have the reward of having induced the more extended culture of the flowers they love in the gardens of hundreds of persons whose lives are made happier and homes brighter thereby. That is or should be the ultimate object of the promoters of flower shows special or general, and so long as that object is apparent there will be no lack of interest in their work.

Exhibitions of Auriculas, of all flowers, are among the most beautiful spectacles that can be provided for the delectation of the public. They are also instructive. It is there better than anywhere that the inexperienced admirer and young cultivator may ascertain the characteristics of high-class flowers, and the defects of blooms relatively inferior. Information is readily given by experts, florists' "secrets" having long since been relegated to obscurity. The shows in question further afford, or ought to do, an opportunity for agreeable gatherings of friends who may derive enjoyment from intercommunion and pleasure from the "simple source of flowers." If they fail in this respect they are at once shorn of an important element in contributing to their permanency and success; as far as possible they should be chosen as favourable occasions for removing grievances, real or fancied, and mitigating asperities, and those who act in a contrary spirit incur a grave responsibility. This we are positive is the conviction of the majority who, like ourselves, wish to see floral societies prosper and harmony prevail throughout the horticultural ranks.

TRANSPLANTING ONIONS VERSUS THE MAGGOT.

It is stated in an old edition of the "Encyclopædia Britannica" that transplanted Onions "remain free from wireworm No. 1856.—VOL. LXX., OLD SERIES.

or rot, while those left in the original seedbed are frequently much injured by both." And further on in the same article, "Possibly the soot puddle may also be beneficial, by tending to repel the larvæ till the bulbs be too strong to be attacked." Have the readers of the Journal found that transplanted Onions are free from grub? I live in a district where nearly every cottager has an allotment garden, and nearly everyone thinks he knows all about the Onion grub. One ascribes his freedom from the pest to transplanting, another to the fact that he never stirs his Onion beds after the seed is sown more deeply than is necessary to cut down weeds. I remember some years ago reading and making a memorandum of an article in a gardening paper in which the writer stated that mulching between the rows of Carrots and Onions with short grass would effectually prevent damage by grubs. This remedy I have tried and found wanting. While reading the article on Onions in the "Encyclopædia," I thought there might be some truth in it, as in transplanting these the bulb is carefully kept above ground. At any rate, where transplanting is followed there is less of the bulb below the surface of the soil than where they are sown in permanent beds, and consequently there is less room for the grub to attack.

Rather more than a year ago I took the following note from a gardening paper:—"To half a pound of soft soap add a pint of hot water, thoroughly dissolve the soap, then add half a pint of paraffin, stir well, then add two quarts more of hot water, put into a stone bottle, and shake well before using. This mixes readily with hot or cold water, and for syringing or sponging can be diluted as necessary." I not long ago sponged a large plant of *Croton pictum* with the above mixture, using rather less than a wineglassful to three gallons of cold water, and not a leaf was damaged, and I intend trying the same upon Onions and Carrots this year if they show signs of grubbing. I am acquainted with a market gardener who planted about two acres of newly trenched land with Raspberries and Strawberries which were soon attacked by grubs. He tried sowing soot to no purpose. At last to save the plants he set men to work with trowels to take away the soil from the roots, pick up what grubs they could, and before returning the soil, to give each root a handful of soot, and in this way, at a cost of £20, he saved the plants from destruction. If the mixture I have mentioned above should answer, it will be both cheaper and more quickly done than the plan he adopted. An amateur who grows remarkably good crops of Onions says that transplanting and constant treading between the rows and as close to the bulb as possible will effectually prevent the attacks of grubs.—T. A. B.

ROSE MARECHAL NIEL.

THIS much-appreciated Rose will not live upon any stock now employed for a longer period than five or six years. A few instances to the contrary may be pointed out, which I readily grant; but these are exceptional cases, for where one plant is found in good health and vigour for a longer space of time than that mentioned, hundreds succumb in less than half. The Manetti is a useless stock for this Rose, and very few indeed are now worked upon it, as it is exhausted in one year by such a strong luxuriant grower, even if planted deeply in order to induce roots from the junction of the scion and stock. A few years ago I planted out nine growing Roses on this stock from 6-inch pots. They grew well, making shoots 20 feet in length or more, but the whole with one exception died the following spring as soon as they started into growth, for upon examination the stocks were found to be dead. The one that lived had produced roots from the union of the scion with the stock, but not sufficient for it to make much progress the second year, and was in consequence pulled out. The longest time I have had a plant live on the Briar has been five years, but its progress was slow. It commenced to canker badly, and has done but little good since.

I am distinctly in favour of Roses upon their own roots. I believe they will live longer and flourish better than when upon stocks. I have two plants now five years old that have up to the present time done well; but upon one there is now a slight trace of canker, although the growth made during the past year has been remarkably strong. My experience up to the present justifies me in saying that the *Marechal* is one of those Roses that enjoys a fast life and a short one. I do not believe, whether grown upon its own roots or worked upon a stock, that any dependance can be placed on it living for any great length of time: still it is worth cultivation, for no other variety with which I am acquainted, the old "Glory" excepted, will yield a greater per-centage of fine flowers with less trouble. The only system by which success can be attained is to keep on hand a stock of young plants, which are readily raised from cuttings, for no Rose will strike root with greater freedom. If the roof

of a house has to be covered, why might it not as well be covered with, say, half a dozen plants as to wait for a longer period of time and cover it with one large specimen? The former is decidedly preferable, because the one might die and then cause a break, but with a number of plants they would not all be lost together. If one or more showed symptoms of disease they could be pulled out and young vigorous plants put in their place.

This is a valuable Rose for pot culture, and should be raised annually for early flowering and then conveyed to the rubbish heap; or if strong shoots issue from the base they can be cut close back and retained for a second year. Well-ripened plants require but little forcing, and blooms may be had in quantity during February from plants raised the previous spring. Shoots in a single season will often attain a length of 25 feet, which will produce on an average twenty blooms. If a dozen plants are grown the figures given will perhaps be the least number obtained from any of them.

Those who have established plants will now be able to take good cuttings. Wood not half ripened should be selected; soft shoots about 3 inches in length slipped off with a sharp knife close to where they join the old wood will also root freely at the present time. If firmer wood is employed the cuttings will be much longer forming roots, and a much greater per-centage of deaths will be the result. If the cuttings have two joints that will be ample; both leaves should be left upon them, and the top eye only out of the soil. They must be inserted in sandy soil or all sand in pots, pans, boxes, or handlights. Whichever are used they should be covered with bellglasses or sheets of glass, so as to exclude air, after a good watering has been given, if successful results are to follow. After insertion the cuttings should be stood in a heated structure shaded from strong sun, and in about three weeks they will have formed roots. When in this stage air should be admitted gradually until they can have full exposure, and the sooner afterwards they are placed singly into 3-inch pots the better.

After potting they may be returned to the structure in which they were rooted, and kept in a close frame for ten days or a fortnight until they recover and commence rooting afresh. In a warm moist temperature they will soon commence growing vigorously, and should be supplied with an upright stake. When about a foot high they will have filled their small pots with roots, and should be transferred into others 3 or 4 inches larger, and when established in these pots give them positions where the temperature is a little lower. It should, however, be lowered by degrees until they can endure a cool house where air is admitted freely by the time they have filled their pots with roots. Care must be taken not to move them from a warm to a cool house without gradual preparation, or they will not make any progress for a long time. The young plants should by this time be 4 or 5 feet high and ready for 10-inch pots. When established in these some of them will continue to extend their leading shoots, while others will produce strong suckers from the base, which should be encouraged, for they will extend with rapidity and make better plants before autumn than those that have extended from the top eye of the cutting. To grow these plants well they will not need larger pots than those named, and from the time they are placed in their flowering pots they should be trained under the roof of a house with a southern aspect until they are well ripened in autumn.

In potting the soil should be pressed firmly and the roots of the plants should be disturbed as little as possible, only removing the drainage. From the first they must not remain in their pots until they are crammed with roots, but should be shifted as soon as the roots have reached the sides of the pots. If checked by this or any other cause they seldom make satisfactory progress.

The soil that will grow them well is rich fibry loam, a seventh of manure, and about a 6-inch potful of bonemeal to every barrowful of soil and nearly the same quantity of soot, with a little sand. For the first two pottings a little leaf mould may be employed with advantage, for it will assist them to make a quick growth. If planted out use only loam, and substitute for the manure quarter-inch bones, which are better, for the soil sours quickly when manure is employed.

Careful watering is needed for a time after potting, but when they are rooting freely liberal quantities must be given them; in fact, in no stage, not even during the winter, should they be allowed to become dust dry. When their pots are full of roots weak liquid manure may be given every time they require water. Better even than supplying stimulants in a liquid state is to sprinkle some suitable artificial manure on the surface soil. While growing the plants should be syringed liberally to keep red spider in check, but there is not much fear

of this or aphides appearing while the plants are growing vigorously.

When well ripened in autumn they should be taken down from under the roof and five strong stakes placed at equal distances round the sides of the pots, the growths trained round them, and then stood outside until the approach of sharp weather. This further ripens, and is the means of inducing them to rest early, which is the secret of success, for they will start earlier and better into growth afterwards. If the blooms are wanted for cutting the system of training given is the best, for they will break from every eye along the shoot.

When the plants are raised for the express purpose of planting out it is best done while they are in active growth, in fact when ready for placing in their pots. By planting when in this condition they get well established before the winter, which is important, in order to secure a strong and vigorous growth the following year. The *Maréchal* being such a free-flowering Rose the young plants should not be allowed to carry the quantity they will produce the following spring after planting, the whole if possible should be removed, which will be found to be very beneficial to them. The quantity of flowers they will carry if allowed to remain exhausts the plants to a much greater extent than many suppose.

Pruning can be conducted on two principles, but the one by which the greatest quantity of bloom can be obtained should be practised. All the strong growths that issue from the base of the previous year's wood should be retained and laid in, while some of the weaker shoots can be shortened or cut out to make room for them. The side shoots or twiggy growth may, if likely to become crowded, be cut out or shortened back to one joint. The very weakest shoots are taken out, while others are only shortened back or thinned. Under this system of pruning more blooms will be produced than would be the case if the plants were cut hard back and had to produce again long strong shoots to fill the space. This plan need only be adopted if large flowers are required in preference to a greater number.—WM. BARDNEY.

PETROLEUM AND ITS USES.

ALTHOUGH so much has been written on this as to its value in horticulture there are many who have not commenced using it, and, on the other hand, there are others who have long since discarded it and taken up other more expensive and less effectual insecticides, simply through accidents occasioned by the paraffin being injudiciously applied. Great care is necessary in the preparation previous to its being used on tender plants, as without this success is very uncertain. I have used it now for several years successfully on many stove and greenhouse plants, such as *Crotons*, *Dracenas*, *Gardenias*, *Stephanotis*, *Azaleas*, and *Camellias*, and therefore I am in a position to say it is a safe and effectual remedy against mealy bug, scale of all kinds, and thrips. I cannot assert it is destructive to red spider, and it is of but little value for aphides, at least such is my experience; but there are other very simple means for the destruction of these pests.

In the first place water heated to 110°, or as hot as the operator can bear it, should be used, as at this temperature the oil mixes better, and it will also be more effectual. Two ounces to a gallon is considered sufficient for most of the insects above mentioned; and in measuring, for want of something better, we have an ordinary 6-oz. medicine bottle, using this filled for four gallons of water. Two syringes are set to work, and after the whole has been thoroughly mixed by forcibly discharging the contents of the syringe into the vessel used for the purpose several times, one man then commences to syringe the affected plants with the mixture, while the other continues stirring the contents of the pot with all the force possible, otherwise the oil floats on the surface. Where one syringe only is available every third syringe should be applied to the plants. Some use soft soap with the oil, but, after trying both ways, I fail to see any advantage from using the former substance when the latter is sufficient by itself. Dull weather should be selected for applying petroleum, or in the evening after the sun is off the house, as I have found the sun affects the oil in such a way as to be very injurious to plant life. It is the safest plan to wash the oil off with clear water some time after, although in dull weather we have frequently left this on them without any apparent harm. In mild weather we carry our plants outdoors and lay them on their sides to clear them, as in this way any insects that fall off uninjured can be left outside.

As a winter dressing for Peaches the trees here have received nothing more than this for several years, and we are never troubled with either scale or bug now. Care is taken to wet every part of the tree, and this is carried out in the same manner as in the case of plants. The time taken in applying this on Peach trees is very little compared with the old system of brushing all the main stems of trees

with various other mixtures, not to mention the fact of its being so much more effectual, while several of the latter are equally as dangerous if not applied carefully.

Climbers such as *Stephanotis*, *Thunbergias*, *Tacsonias*, and *Passiflora*, when affected with mealy bug, we look over frequently, applying a mixture of water and paraffin in about equal parts with a feather; a touch from the tip of the latter dipped in this proves instant death to this pest, and by adopting this plan we can keep free from this much-dreaded insect. For sponging, too, paraffin is in request, this leaving more easily the desirable and beautiful gloss on the leaves, and also causes the dirt to separate more easily; but in this case soap is used with it, the former in the proportion of about a teaspoonful to a gallon of water, care being exercised to stir it well, so as to avoid taking the oil from the surface in the sponge.

If petroleum of good quality is obtained, and strict measures taken in its preparation, no one will have occasion to abuse it, as on these two points success depends. We use it here for cleaning the glass and woodwork of the houses, and find it more speedy in its action than soap alone.

In the fruit garden petroleum is indispensable, many gardeners using this for soaking various kinds of seeds to protect them from the attacks of birds and mice; but we find it is not proof against the latter by itself, but if a little red lead is shaken over the seeds when wet they will not suit their tastes so well. It is thought by some that the Celery and Onion flies can be partially checked by syringing this over the plants occasionally in the evening, and for American blight on Apple trees it is a well-known remedy, as well as for the scale that infests Pear trees.—A YOUNG GARDENER.

THREE PRETTY COOL HOUSE PRIMULAS.

PRIMULA OBCONICA—known also as *P. poculiformis*—may be allowed to head the list, for it is so charming and floriferous; indeed, when once it commences flowering it is difficult to say when it will stop. I have had a plant in flower since last October, and it looks as if it would continue until next October, and it is now crowded with large heads of pale lilac flowers, each about three-quarters of an inch across. We are indebted to Messrs. Veitch for its introduction, and the Journal was the first to publish an engraving of it. It is not difficult to predict a happy future for the plant, as it is so easily grown, and gives an excellent display, far more than compensates for the small amount of trouble incurred in securing good plants. The plant referred to above was one of a batch raised from seed last March in a cool greenhouse, and grown through the summer in a similar house. I am now about to sow a fresh batch of seed, with the idea of procuring plants for next winter's flowering, and the seed will be treated very much like that of the Chinese Primrose, using well-drained pots filled with light sandy soil. Well water the latter before sowing, strew the seed thinly on the surface and sprinkle a little sand over it, cover the pot with a sheet of glass, and place it on a warm shelf in the greenhouse. When the young plants are large enough they should be potted singly in thimble pots, and afterwards treated like the Chinese Primrose. It is a native of Japan.

Primula floribunda is a little-known gem well deserving its name, for it is impossible to possess a plant which flowers more freely. Commencing in a cool house in September or October it will continue nearly to the same months of the following year unless prevented, which is advisable, or the plants will quite exhaust themselves; and if the blooming is thus stopped the plants may be shaken out, repotted, and grown freely, as I believe this species is nearly a perennial. I have some plants in their third year, and they are now full of flowers. The latter are bright canary-yellow, about half an inch across, arranged in whorls similar to *P. japonica*, but the rows are not so numerous as in that species. It seeds very freely, and there is no difficulty in obtaining a large stock. They are easily raised in a cool house. They are very small, and consequently must only be lightly covered. The foliage is very hairy, and liable to decay if constantly wetted, hence it is necessary to avoid doing so. It is a charming little plant for arranging with small Ferns, very dwarf in habit; my tallest plants are not more than 9 inches high.

P. verticillata.—This species is better known, but very much less cultivated than it should be, as it is so pretty during the early spring months, producing good trusses of sweetly scented bright yellow flowers, with white powdery calyces and footstalks, which are in happy contrast with each other; the leaves are also thickly coated with white powder, and the whole plant has a very distinct, and, to my mind, beautiful appearance. All such plants deserve to be more generally cultivated. I do not wish to recommend the culture of weedy plants, but there are many looked upon with a suspicious eye by gardeners, which would really

brighten and diversify the appearance of conservatories and cool greenhouses.—T.

VEGETABLE MARROW CULTURE.

LIKE Tomatoes, Vegetable Marrows are not grown so much as they should be. Large rough-growing sorts with fruits like cattle-feeding productions are not likely to make anyone grow them for frequent use in the kitchen, but some of the small-fruited varieties are so suitable for the dinner table, and so excellent in flavour, that when once they are fairly and rightly introduced no one would allow a season to pass without having quantities of them. In sending vegetable to the kitchen some years ago we were never asked for a second supply of the large Marrows, but since the small ones have been sent in they are put on the bill of fare repeatedly, and many of them are preserved for winter use. No Vegetable Marrow for the table should be more than 2 lbs. in weight. If two or three times the weight of this they will be coarse and tough, and void of the true pleasing flavour.

In raising young Vegetable Marrow plants a slight heat, such as that afforded by a gentle hotbed or frame, is a great assistance in germinating the seed and pushing forward the young plants; but when the season has advanced so far as this they may be raised under a handlight or in the open, and plants of all descriptions should now be daily exposed to the air, as in a few weeks hence they will be planted in their fruiting quarters. This may be on a manure or refuse heap, as they do exceedingly well on such positions, and they will also succeed on small mounds placed on a south border or any other sunny position. When the compost in which they have to grow is made up chiefly of manure the plants produce thick stems and large leaves in it, but this is not the way to get fine fruits or plenty of them. Robust growths and astonishing productiveness are never associated, but moderate growths and heavy crops may easily be produced. To accomplish this the soil should consist of turfy loam or common garden soil with a small quantity of horse droppings added, and in this it will be found that the plants will make hardy short-jointed wood with small leaves, and one or more fruits at every joint. Many who have seen our Marrow plants with the fruit clustering along the stems wonder why they are so prolific, but it is solely the result of stinting them at the roots. Plants poorly supplied with feeding at first come into fruit very much sooner than those which make a large quantity of soft growths before a fruit is formed.—A KITCHEN GARDENER.

CACTACEOUS PLANTS.

(Continued from page 190.)

ECHINOCACTUS, *Link and Otto.*

(The Hedgehog Cactus.)

THE Hedgehog Cactus genus is one of the largest in the whole family, and the two hundred species comprised in it include some of the most handsome and curious forms in this portion of the vegetable world. They are not so remarkable for beauty and symmetry of structure as the Mamillarias, but the flowers are usually large, brightly coloured, the tints most predominating being yellow, rose, and purple, while many are pure white. The flowers also in numerous species attain a considerable size, almost rivalling some of the Cereus; and as they frequently open for several days in succession they have not the defect of fugaciousness so common in other members of the family. The strangest character connected with the Hedgehog Cactus is, however, the enormous size which some of them attain. It is true they do not grow to so great a height as the Cereus, for few, even of the largest, exceed 4 or 5 feet in height, but they occasionally become excessively bulky, as in *E. Visnaga*, sometimes weighing as much as a ton, though there is every gradation from that to species as diminutive as the Mamillarias. The majority of globular stems like the Melocactus, with more or less strongly marked ridges from the summit to the base, usually slightly spiral, though frequently nearly vertical. In a few species these ridges are broken into a series of tubercles, which are sometimes nearly as distinctly separated as in the Mamillarias, and in others are partly confluent, until in the extreme cases they can only be traced by slight prominences upon the ridges. Whether moderately or strongly developed these projections are termed tubercles as in the other genera, and each bears a cluster of spines, which vary in size from extremely small points that are scarcely discernible to gigantic and formidable horny spines 3 or 4 inches in length, straight and rigid, or hooked at the point; they are also sometimes in two series, the outer spreading and the inner erect. These furnish characters which assist in determining the species, and Labouret has given an elaborate system of classification, founded chiefly upon these appendages.

The flowers are produced from near the apex of the younger tubercles at the upper part of the stem, and are borne just above the cluster of spines. Sometimes they are clustered in a dense woolly substance somewhat like the cap of the Melocactus at the summit of the plant. The calyx forms a tube varying in length, being sometimes very long and funnel-shaped; it is usually scaly, the scales gradually passing into the

lobes of the calyx, and these in turn into the petals, all the parts being very numerous, and not readily distinguishable from each other. The stamens are in great numbers, the filaments being united to the tube of the calyx. The style is columnar, the stigma with many rays, and the fruit is berry-like, to which the lobes of the calyx frequently adhere.

By various authors a few of the species have been separated under other generic names, as *Malacocarpus* of Salm Dyck, *Gymnocalcium* of Pfeiffer, and *Astrophytum* of Lemaire; but these have been found to be insufficiently distinct, and are now united with the *Echinocactus* by Hooker and Bentham.

The species are widely distributed, being found in Mexico and various parts of South America, but in the first-named country and adjoining regions they chiefly abound. There they are found in arid stony or rocky places, with very little soil for the roots, exposed to a high temperature in the summer and a much lower one in the winter—indeed, some endure frost and snow with such little injury that they might be reasonably expected to be hardy in this country. Some have been found to resist our winters, but comparatively few have succeeded at present, and doubtless the chief reason for this is the much greater amount of moisture in the soil and atmosphere.

Culture.—In growing the majority of the *Echinocactus* the chief points requiring attention are providing a well-drained soil, as they are all impatient of the least excess of water, and regulating the supply of moisture with much care. Most of the Mexican species in particular produce but slender and few roots, and only need small pots, as an excessive quantity of soil is positively injurious. These, too, will succeed in a temperature between 45° and 50° during the winter months, but then require scarcely any water.

Propagation.—Few of the Hedgehog Cactus produce offsets, and are therefore not readily propagated in that way. When, however, the upper part is injured, or in the case of the columnar species if that portion is cut off, the lower part of the stem often produces several shoots like other Cactæ, and these can be treated as previously advised for offsets. In Mexico and elsewhere in North America certain species are very abundant in particular districts, some growing amongst the grass and scarcely visible, and travellers relate that where these are injured by fires or cattle they form a great number of shoots, becoming closely branched tufts or cushions of considerable size. The majority of the species can be easily grafted upon the *Cereus* or other genera except the *Opuntias*, to which they do not unite readily. Grafting is, however, unnecessary in most cases, as, except the very delicate species or abnormal crested varieties, they are best on their own roots. A few years ago Mr. Peacock had an interesting specimen of *E. Pottsi*, which was grafted upon three stems of *Cereus tortuosus*, and being raised several inches above the surface of the soil it had a very strange appearance.

SELECT SPECIES.

In so large a genus it is obvious that only a few can be named in these notes, but some of the most distinct of these in cultivation have been selected. Collections in general do not include perhaps more than a fourth of the entire number known.

ECHINOCACTUS BREVIHAMATUS, *Engelmann*.—A pretty and distinct species from San Pedro, very noticeable for the prominent globular tubercles, which might almost cause it to be taken for a *Mamillaria*. The stem is cylindrical, 5 to 6 inches high, and 4 to 5 inches in diameter. The spines are in two series, those of the ray twelve, half to three-quarters of an inch long, the central one 1 inch long, hooked at the point and yellowish brown in colour. The flowers are about 1 inch long, of a pale rose tint, but have a deeper coloured mid-vein, which brightens the flowers considerably.

E. CERATIOTES, *Otto*.—An elegant plant, which from its columnar growth and numerous rounded ridges has a very distinct appearance in a collection. The best specimens at Kew are 2 feet high, 8 inches in diameter at the base, and nearly as much at the top, except where young growth has been recently made. The ridges are twenty or more in number, half an inch deep, nearly as much across, somewhat rounded, and deep green. The spines are in clusters of twelve or more, 1 inch apart on the ridges, seven or eight of the outer spines being white, fine, and hair-like, four or five inner ones being rigid, 1 inch long, and of a bright reddish colour on the young growth, which has a pretty effect. It is a Chilean plant, and has been in cultivation for more than thirty years, but is rather scarce.

E. CYLINDRACEUS.—A Mexican species of formidable appearance, furnished with long and powerful spines, which interlace over the plant in a strange manner, and affording it a most effectual protection. The stem is globular, in the largest specimen I have seen about 6 inches high by the same in diameter. The spines are horn-like, with nodes like the antennæ of some large insects. They are 2 to 3 inches long, interlacing flat on the surface of the plant. Others are spreading or curved, 3 to 4 inches long flattened, with a reddish tinge. As a curiosity this is one of the most striking of the genus. It was introduced from the Colorado district in 1877, but is scarce in collections.

E. ECHIDNE, *De Candolle*.—A distinct and rather attractive plant, which owes its name apparently to its cylindrical form and abundant spines, and to the former character probably is due the name of Viper Cactus which some have applied to it. The stems are 6 to 12 inches high, 6 inches in diameter, with eleven to twelve ridges 1 inch deep, and spirally arranged on the stem. The spines are half to 1 inch long, rigid, greyish white, and tipped with reddish brown, and are in clusters of seven to eight, about an inch apart on the ridges, their base being surrounded by a thick grey down. The flower is of moderate size, and bright yellow.

E. ELECTRACANTHUS, *Lemaire*.—Distinguished by a bold appearance that renders it quite unique and easily recognised. Well-grown plants are from 18 inches to 2 feet high, and 1 foot in diameter, with twenty-two prominent angular ridges 1 inch deep and the same in width, deep green, but having a cartilaginous edge. Upon this are borne the spines in clusters of nine, 2 inches apart; the spines are equal in size, 1 inch long, rigid, horn-like, and

yellowish, the central one bright red at the base. The flowers are clear yellow. It is a native of Mexico, whence it was introduced some thirty or forty years ago.

E. HORIZONTHALONIUS, *Lemaire*.—A beautiful species, which, according to Engelmann, is found growing in strong soil at the summit of hills from Pecos to El Paso and north to Dona, and where it flowers freely from April to July. It varies greatly in size, but is globular in form, with nine to ten thick ridges, on which the clusters of spines are very closely set, the number usually being seven, thick and rigid. The flowers are funnel-shaped, purplish pink, the sepals being tipped with a darker shade of purple, and have a pretty effect when opening in the sunlight. The stamens are very numerous, and in some flowers as many as 1200 have been counted; they also have a rather pleasing appearance, the yellow anthers contrasting with the white filaments.

E. INGENS, *Zuccarini*.—This is one of the few *Echinocactus* which furnish any product of service to man, and even in this case it is far from being in general use. Several species produce a woolly or silk-like substance at the summit of the plant, but in this one it is particularly abundant, and in Mexico, according to Dr. Parry, it is collected and employed for stuffing pillows. The filaments composing it are not long, but soft and silk-like even in colour, somewhat resembling a similar product found round the base of the fronds in some species of *Cibotium*. In the Kew museum are good specimens of the substance. Cultivated plants are 8 to 10 inches high, of globular form, with twenty to twenty-one ridges 1 to 1½ inch deep, spirally arranged. The clusters of spines are half an inch apart, and contain twelve to fourteen grey spines 1 inch long.

E. LONGIHAMATUS, *Galeotti*.—Remarkable for the length of the spines which give it a very peculiar appearance. It is also interesting for a character which may probably have some bearing on the fertilisation. It is well described by Engelmann as follows:—"The flowers form a groove

Fig. 77.—*Echinocactus rhodophthalmus*.

just above the spines, separated from the spiniferous areolæ by two to five obtuse cylindric glandular bodies, which often exude a clear viscons liquid. I find them also in *E. setispinus*, *E. Emoryi*, and numerous others, and they correspond no doubt with the glands in the groove of *Mamillaria Scheeri* and others. They appear with the flower, and are soft and fleshy at the time, afterwards they become hardened, of the texture of the spines themselves, and persistent." It is difficult to tell what is the exact purpose these serve, as, beyond the fragrance of the flowers and the abundant stores of pollen, there are few temptations for insect visitors in most Cactaceous flowers. *E. longihamatus* is a native of the Rio Grande district near the Pecos and San Pedro rivers, and it was introduced by Galeotti in 1851. The stem is globular, 2 to 12 inches high, dark green or glaucous, with thirteen ridges of circular mound-like tubercles 1 inch high. These are about 1 inch apart, and bear six to fourteen strong rigid spines each, red when young, and brownish grey or black afterwards; the central one is sometimes 4 inches long, and terminates in a hook. The flower is 3 to 4 inches in diameter, with narrow yellow petals and greenish sepals. The fruits are described as "green and acid when young, but sweet when ripe." This species is particularly well grown in the Oxford Botanic Garden collection, which includes several large and handsome specimens.

E. RHODOPHTHALMUS, *Hooker*.—A neat and pretty species of moderate growth and flowering very freely. The stem is cylindrical, somewhat columnar in form, 6 to 8 inches high, 3 to 5 inches in diameter. There are eight to nine ridges closely set together, and upon these are the clusters of nine spines, each about 1 inch long, the central one the largest, the others spreading. These are in their earliest stages of a purplish hue, but as they grow older they lose the colour and become pale. The flowers are borne at the summit of the stem, are 3 to 4 inches in diameter, formed of narrow spreading petals, the colour being a pleasing shade of rosy crimson, much darker at the base, thus forming a ring of colour

which greatly improves the appearance of the flower. The species is a native of San Luis Potosi in Mexico, and was introduced to this country by F. Staines, Esq., in 1847. It flowers during the summer months very freely, and is worth a place in any collection, but still continues rather scarce. The woodcut, fig. 77, is a reduced representation of the plate in the "Botanical Magazine," t. 4486, published in 1850. A variety named *ellipticus* was also figured in the same work subsequently, but it differs very slightly from the type.—L. CASTLE.

(To be continued.)

THE GRASS GARDEN.

I AM induced to send a few notes on gardening on grass from the great beauty displayed by such a simple flower as the common Primrose at the present time. Primroses grow here by thousands—in clumps, in broad masses, in detached straggling groups, or scattered singly in portions they have not as yet thoroughly colonised. No form of spring bedding is so simple, so satisfying, so effective, so cheap. The very atmosphere is redolent with Primrose scent, and even when we are not looking at the varied coloured masses we are quite sensible of their presence. I do not intend to write a long article detailing every step to be taken in order to beautify stretches of grass in spring. I would rather drop a few hints, and leave the rest to those who wish to carry out the principles in their own case.

A specially bad practice to guard against is that of placing plants singly over a large expanse of grass. It is not only much better, but it is really the only sensible plan, to plant out closely in clumps or round and underneath trees. The flowers are in this case effective at once, and attract attention without having to hunt them out, as is necessary when planted singly. Recently I saw some Daffodils set out in the manner here condemned. A single bulb had been put out here and there, and the whole result was a feeling of loneliness, produced by the want of taste, which would have gathered the whole of them into a few square yards, and thereby have made an oasis in a desert, which the woe-begone little plants made only the more dreary.

The present is a good time to prepare a stock of Primroses, Polyanthuses, and Cowslips, by sowing good breadths of seed in the kitchen garden. Some light vegetable or leaf soil will be of much advantage. Where time is to spare the seedlings will be rendered much stronger by pricking them out singly on a north border. Our system of planting these is to set a man with a spade to cut a like mark on the turf, gently easing it up as he removes his spade the second time. The plants are put into the little trench thus made, the turf firmed down with the foot, and the planting is completed. Polyanthus *Narcissus* which have been forced should now be clumped on suitable places. Those who like Tulips will also find them do well if transplanted now. In our poor soil I find it is necessary to lift as much turf as is necessary to include the plants intended for one position, cultivate the ground, plant out, and again relay the turf.

It will be found best to confine the *Narcissus* to a few good types, so many of the expensive new kinds are either very like older ones, or hardly worth growing at all. *Narcissus pumilus* is the earliest, and a pretty dwarf kind, looking well on grass. Good varieties are also *N. bicolor Horsfieldi*, *N. b. primularius*, *N. incomparabilis*, and the double kinds of this, *N. lorifolius Emperor*, and *N. l. Empress*, *N. maximus*, *N. telamonius*, the varieties of *N. Tazetta* and of *N. poeticus*, and *N. jonquilla*. Other indispensable flowers are Snowdrops, which do best in shady positions. Crocuses we fail to get to do, field mice completely clearing these out. Like the Primroses all these are best grown in detached clumps and masses. A few of them are pretty in portions of the Primrose plantations, but only sparingly.—SYLVANUS.

DECORATIVE PELARGONIUMS.

DECORATIVE Pelargoniums are very useful and free-flowering plants. The flowers have not the perfect form of those designated Show varieties, but they are much superior from a decorative point of view. It is chiefly through the exertions of the London market growers that we have these Pelargoniums, most of them having been raised in such establishments. Gardeners that have not been through Covent Garden Market whilst these plants are in season would be amazed at the numbers. From the present time until the end of June thousands of plants may be seen in 48-size pots with about eighteen trusses of bloom fully expanded, and as many others coming on, with sturdy foliage down to the rims of the pots. In establishments where Pelargoniums are a speciality rows of low span-roof houses, with ample ventilation and very light, may be

seen. The plants are also placed near to the glass to keep them sturdy.

The present is a good time to take the first batch of cuttings. These should be taken from plants that are adapted for early blooming. The following are excellent varieties:—Scarlet Defiance, Kingston Beauty, Le Géant, Mrs. Lewis Lloyd, Albion, Venus, Madame Favart, Lucie Lemoine, Maid of Kent, Emilie Everard, Virginalis, Scarlet Gem, and Pink Perfection. The same varieties, with the following added, are useful later in the season:—Duchess of Bedford, Triomphe de St. Mandé, Regalia, Prince of Wales and Digby Grand. The cuttings should be inserted singly in small 60-pots, the soil consisting of equal parts of leaf soil and loam with a little sand. Place them in a temperature of 55°, when they will soon root. The later batch will strike readily in a frame or pit.

After the cuttings have rooted freely harden them; take out the points of the shoots after they have grown enough to require it. When they have started repot into 48-size pots; if they are to receive another shift repot first into 54-size pots and next into 32's. The soil should consist of three parts fibry yellow loam (not sifted), one part dried horse manure that has been prepared by being turned over frequently, and about an eighth of leaf soil. The leaf soil and horse manure must be sifted. Pot the plants very firmly, and place them in cold frames or pits close to the glass. After they have rooted in the soil ventilate freely, removing the lights on fine nights. Two stoppings will be sufficient; at the last care should be taken to shorten all the shoots on the plant at the same time, so as to insure an even growth.

By the end of September the plants must be housed, placing them, if possible, in a light position and free ventilation. The earliest varieties must be kept growing all through the winter. They must also receive a little heat; about 50° will suit them admirably until the buds are well advanced, when 55° will be the best temperature to insure early flowering. On the first appearance of the bloom buds a little liquid manure will be beneficial, or a little Standen's manure. As they increase in growth they will require liberal treatment until they show colour, when only clear water must be given. Ample ventilation is needed all through the winter, at least on all favourable occasions, to keep them sturdy. The later plants must be kept cool and receive very little water during the winter, at least up to the middle of February. The plants must on no account be crowded, or they will become tall with little foliage at the base. The plants should also be fumigated about every fortnight to keep aphides in check.—A. YOUNG.

CHLORIDE OF POTASH.

IN a recent number (page 285) is an account of a powder for manuring plants, and one of the ingredients is chloride of potash. On reading the article it struck me that there is no such substance as the above-mentioned, and I am borne out in my opinion by a druggist to whom I have applied. I conclude the writer means chlorate of potash, and if so it shows that "a little knowledge is a dangerous thing;" for in these drugs, although the terminals of the names are a good deal alike, the substances are very different, and a harmless one may be next kin to a strong poison.—MEDICUS.

[The writer of the article in question has perused the above letter, and the following is his reply:—

"I can scarcely understand 'Medicus' when he states there is 'no such substance' as chloride of potash, and then goes on to say the 'substances (chloride and chlorate of potash) are quite distinct.' Chloride of potash is obtainable from any dealer in manures. The commercial salt is obtained from the Stassfurth mines, and is considered one of the best mediums for presenting potash to the soil. It is found in all fertile soils, and is also present in plants. The writer has repeatedly proved it to be beneficial mixed with other manures and given to plants. A chemist can produce chloride of potash by dissolving caustic potash in hydrochloric acid. We believe that both chlorate of potash and the chloride result from a current of chlorine gas being passed through a strong solution of caustic potash, the latter being separated from the former by crystallisation. 'Medicus' doubtless appreciates the value of the chlorate to people who are subject to sore throats; of the chloride it may be said that it is equally valuable to people suffering from garden on the brain."]

ANEMONES.

THE Windflowers, as the Anemones are popularly termed, appeal to the taste of all lovers of flowers, from the florist with his severe and, if I may use the term, classical ideas as to form and colouring through the medium of *A. coronaria* and *A. hortensis*, with their numberless single and double forms. The lover of the wild garden may, on the other hand, be gratified by sheets of the white *A. nemorosa* or the bright golden yellow of *A. ranunculoides*, the former so lovely when seen in the open

spaces of the shrubbery or near a woodland walk in association with the wild Hyacinth; while the cultivator of alpine plants may be pleased by the silky blooms of *A. vernalis*, or in the recesses of his peat bed the double forms of *A. palmata* or *A. thalictroides*. For general border decoration and cutting, too, what can be more valuable than the stately *A. japonica* and its white variety *Honorine Jobert*? who, though far behind the other varieties in the order of their arrival, are if possible even more valuable on that account, coming as they do at the close of a long procession of beauties more or less pretentious, commencing in January with *A. angulosa* and lasting with but slight intermission until October or even November.

The culture of most of the species and varieties is very simple, a few only needing any special soil or attention, and by humouring these in a few of their special requirements no one need despair of success with even the most fastidious. The majority prefer a tolerably rich light loamy soil, deep and well drained when possible. In plants grown on rockwork this cannot be too strongly urged, as many alpine plants have long roots, and being often, from their position, exposed to great sun heat, the importance of a deep mass of soil for their roots to ramble in is obvious. Most of the species may be easily propagated either by seed or division of the roots. The latter method may be practised at any time during the resting season, but preferably from January to March, according to the mildness of the season. *A. alpina* and its variety *A. sulphurea* do not submit kindly to removal or division, and the greatest care should therefore be taken to avoid breaking the small fibres which spring from the long and strong roots, and also to secure as good a bud as possible to each portion, as both of these are often two or even three years before making vigorous growth after being so treated. *A. japonica* and its varieties emit shoots so freely from all parts of their roots that it is only necessary to cut the roots into pieces about an inch in length, and place them in a box or pan in any light compost, covering them with about half an inch depth of soil, to produce as many plants as may be desired; in fact, this property of producing suckers is so pronounced in these varieties that in many gardens were it not for their great beauty they would be voted a nuisance. The varieties of *A. coronaria* and *stellata*, if carefully divided with a bud to each piece, will bloom the first year nearly as well as established plants; but care should be taken not to allow them to become either very dry or very wet, or they will decay and so cause loss and annoyance.

The seeds consist either of roundish bodies terminating in long feathery tails, or are of a roundish somewhat flattened shape, tailless, and enveloped in a downy substance which causes them to cling together in such a manner that it is only by rubbing them for some time in either sand or finely sifted soil that they can be disengaged sufficiently to allow of their being sown at all evenly. The seed should be sown if possible as soon as ripe; if not, then about February or March in pots or pans of light soil, and covered with about a quarter of an inch of very finely sifted material and placed in a frame without artificial heat, which should be kept as dark as possible until germination has taken place, when they should at once be removed to lighter quarters. They should when practicable be allowed to make their first year's growth without removal, and when at rest may be planted out in their final position in the border or rockwork. Although not wishing to deal with the subject of florists' Anemones, which has been treated of by some of our best authorities, I may mention that by purchasing a packet of mixed Anemone seed and treating them in the manner described above wondrous effects of colouring may be obtained by many who would not desire to grow the choice and expensive named varieties.

In describing the species in detail it will not be necessary to consider the subject from a strictly botanical point of view, as in writing as a gardener and to gardeners it is more convenient to note general resemblances in form, colour, and habit of growth than to inquire into the real affinity which often exists in the essential organs of the plants. It may be perhaps as well to select some well-known species as a type around which to group other species and varieties having the greatest general resemblance to it. The various groups are—first, *A. pulsatilla* section, containing amongst others *A. pulsatilla*, an alpine well marked by having the seeds ending in long feathery tails and having thick somewhat fleshy roots. Second, the *A. nemorosa* section, with seeds ovoid and tailless and the roots tuberous; examples, *A. nemorosa*, the common Wood Anemone, and the florists' varieties. Third, the *A. sylvestris* section, having more or less compressed tailless seeds and the roots a mass of small fibres; types, *A. sylvestris* and *narcissiflora*. Fourth section of *A. japonica*, consisting of that species and its varieties, easily

distinguished by their large Vine-like leaves and autumnal blooming. Fifth, the *A. Hepatica* section, proposed as a distinct genus by Dillwyn and very frequently spoken of as such in nurseries. Sixth, *Anemone thalictroides* and its double variety called *Thalictrum anemonoides* by Michaux. Both of these last sections were, however, classed as *Anemones* by Linnaeus, and this decision is, I believe, confirmed by the best modern authorities. I may here state that I shall only deal with such species and varieties as are likely to be of use in the decoration of our gardens, and are to be found at present in nurseries or private collections, although some may be still very rare.—G. GUTHRIE.

(To be continued.)

At a general meeting of the ROYAL HORTICULTURAL SOCIETY, held last Tuesday, Maxwell T. Masters, M.D., F.R.S., in the chair, the following candidates were unanimously elected Fellows of the Society—viz., Alfred Gray, Henry Benjamin May, F. W. Wood, J. J. Woods, C.E. The following letters of condolence to Her Majesty the Queen and reply was read to the meeting:—

“Royal Horticultural Society,
“South Kensington, S.W.
“April 12th, 1884.

“Lord Aberdare presents his humble duty to your Majesty, and begs on behalf of the Royal Horticultural Society to express their deep grief and heartfelt sympathy with your Majesty and the Royal Family on the death of H.R.H. the Duke of Albany; a Prince whose great gifts and noble qualities had stirred in them as in the whole nation a sense of respect and admiration, which deepened as they watched the development of his character, and marked his determination to walk in the footsteps of his illustrious father, and to use his high rank and influence as instruments for improving the condition and ennobling the lives of his fellow countrymen.”

In reply to the above the following was received:—

“Windsor Castle,
“April 15th, 1884.

“DEAR LORD ABERDARE—

“I am commanded by the Queen to ask you to thank the Council of the Royal Horticultural Society for their kind and touching address.

“The Queen is very sensible of the warm feeling shown by them for her sorrow, and is much gratified by the terms in which you have alluded to her son.

“Yours very truly,
“HENRY F. PONSONBY.”

— A CORRESPONDENT has sent us a remarkably fine truss of the beautiful TEA ROSE NIPHETOS, but the letter accompanying it has been inadvertently mislaid. We shall be obliged if the sender of this excellent example of culture will favour us with his name and address, as we wish to communicate with him.

— MR. J. H. KRELAGE, Haarlem, writes in reference to HYACINTH L'OBELISQUE, mentioned on page 284—“This very pretty variety was raised in Holland, probably by the late Mr. Hoogveen, a well-known grower at Haarlem. It was first offered in public sale as his seedling in 1873, and was thus bought by several of the principal bulb-growers, who considered it to be a first-class variety. But it is not abundant in collections.”

— MR. G. ABBEY, Paxton Park Gardens, St. Neots, writes regarding the WEATHER:—“Ten degrees of frost were registered here on Saturday morning (April 19th), and on the morning of the 20th 8° of frost. The only injury so far as can at present be determined is that the shoots of early Potatoes are blackened, but fruit-tree blossom and fruit do not seem at all injured, which may be due to the dryness of the atmosphere, the wind being very keen from the north-east.”

— A DAILY contemporary gives the following note of a REMARKABLE FROST ON THE CONTINENT:—A phenomenal wave of cold swept over part of Switzerland on Monday, 21st inst., without any premonitory warning, the thermometer falling many degrees below zero. The damage to agricultural interests is enormous, and at least one-third of the vintage has been destroyed. It is telegraphed from Macon that a disastrous frost has also devastated the Vines in the Saone Valley, and that the damage is estimated at many millions of francs. In the neighbourhood of London as much as 10° or 12° of frost have been experienced this week.

— JUST on going to press we learn with extreme regret of the death of MR. GEORGE RUDD, the well-known florist, who expired at Undercliffe, near Bradford, on the 17th inst., at the age of fifty-four.

— THE tenth annual Exhibition of the NEWPORT AND COUNTY HORTICULTURAL SOCIETY will be held on July 17th, and a Chrysanthemum Show in November. The prizes at the former are liberal in the leading classes, £12, £8, and £3 being offered for a collection of eight stove and greenhouse plants.

— It is to be feared that the cold and strong easterly winds have impaired the previous bright PROSPECTS OF THE FRUIT CROPS, Plums, Cherries, and Pears especially, which were in full blossom in the south. At Chiswick the splendid Pear trees have been pictures of beauty, but the blossoms are seriously bruised, appearing indeed as if seared, yet the embryo fruit is at present fresh. It is the same with Plums, but unless genial weather follows it is greatly to be feared that much of the fruit will vanish, as Mr. Barron truly observes it cannot in its present stage stand still for long, but must either swell or drop, and the weather just now does not encourage a steady growth.

— AT a GENERAL MEETING of the FELTHAM HORTICULTURAL SOCIETY, which embraces the parishes of Feltham, Bedfont, Hanworth, and Ashford, held on the 16th inst., it was agreed to hold the annual Exhibition of plants, flowers, fruits, vegetables, and table decorations on Wednesday, July 23rd.

— GARDENING APPOINTMENT.—Mr. William Prentice, lately gardener to Rev. S. Allen, D.D., Shouldham Hall, Norfolk, has been appointed gardener to R. Whitehead, Esq., Paddockhurst, Worth, Sussex.

— “M. S.” writes:—“I am glad to see that the CHIONODOXAS are beginning to receive a little attention. I have seen the new *C. sardiensis* in flower, and cannot distinguish it from *C. Luciliae* in some of its varied forms and markings. Whether it will prove distinct or not remains to be seen with mature bulbs. In its present state at any rate it includes *C. Luciliae*, and for that matter *C. Forbesi* also. *C. nana*, although the smallest and least useful as a garden plant owing to its washy-coloured flowers, is very floriferous, and lasts longer than the others, a recommendation which must not be overlooked.”

— THE same correspondent observes:—“A good instance of how the public are deceived by a name is given in the catalogue of a well-known continental nurseryman. Everyone knows the common MARSH MARIGOLD (*CALTHA PALUSTRIS*), as grown in our gardens, with its bright golden yellow flowers. A new one is sent out under the misleading name of *C. purpurascens*, and seeing that such a colour would be an acquisition people will no doubt be led to add it to their collections, although it differs from the common one only in its having slightly purple stems. The flowers are the same.”

— THE MARIANNE NORTH PICTURE GALLERY, opened to visitors to the Royal Gardens at Kew about two years ago, has been a source of considerable pleasure as well as sound instruction to those of the public who have cared to avail themselves of it. The building having been found too small to include a fair representation of the vegetation of the different countries, and the fact of the indefatigable Miss North having lately made a special visit to South Africa in quest of more subjects, it has been found necessary to add a new wing at the back of the old building, and communicating with it by an opening in the wall directly opposite the front entrance. In this are being arranged the Cape paintings, many of the plants in which are new or rare in our gardens. Considerable improvement is noticeable in the hanging of the pictures, each of them being framed separately, showing a broad black frame between instead of the narrow band in the old room. The paintings are exquisite, clear, well defined, and appear on the whole to have a superior finish, lacking nothing that goes to make a good picture, combined with what is of the greatest importance in this class of painting—a faithful representation of the plants and vegetation generally. Among the most prominent is a fine *Crinum Moorei*, *Aponogeton distachyon*, much stronger than we see it in this country; *Nymphaea scutifolia* and several *Nepenthes* very fine, a few Orchids; and one picture is given to a whole colony of Arums. Blue and white *Ipomaeas* are very prominent and quite a feature is the graceful arrangement of several vases of flowers. *Clianthuses*, *Senecios*, *Everlastings*, &c., *Watsonias*, *Sparaxis pendula*, and several *Babianas* are very fine, as also is a fine plate of *Disa grandiflora*, *Kniphofia Quartianiana*, and some Orchids. A cottage covered with *Bougainvillea* and *Roses*, to which is an entrance bounded on each side

with *Lavandula spica*, is extremely pretty, as also are several of the landscapes. We have much pleasure in announcing this new addition to one of the principal features to this far-famed establishment.

— AMONG the Rhododendrons in flower in the temperate house at Kew, the most noticeable is a fine specimen of that superb Himalayan species, *RHODODENDRON AUCKLANDII*. The trusses, which are borne on the summit of the branches, are very fine, and number about a dozen. Before opening they are a fine rose blush, but as they expand changing to pure ivory white. The individual flowers are very large and conspicuous. In the neighbourhood of Glasgow it is said to grow and flower freely in the open.

— AT the COTTAGERS' AND ARTISANS' FRUIT AND VEGETABLE SHOW, to be held by the Royal Horticultural Society on August 12th of the present year, unusually liberal prizes are to be offered, such indeed as have probably never been surpassed at any cottagers' show. Thirty-six classes are provided for all kinds of vegetables and small fruits, the principal class being that for a general collection of garden produce, not less than six kinds of fruits and twelve kinds of vegetables, for which six prizes are offered—namely, £5, £4, £3, £2, £1, and 10s. 6d. These prizes are for competition amongst the various local horticultural and cottage garden societies and allotment holders in the country. The exhibits will be confined to *bona fide* cottagers and artisans, but the classes are open to competitors in all parts of the kingdom. In the other classes the prizes range from £3 to 5s. For two Vegetable Marrows 15s. is the first prize—a remarkably liberal one, but it is not stated whether large or small fruits will be required. In the class for Lettuces 15s. is also offered, but the number of heads to be shown is not stated, apparently an oversight. In the majority of classes the first prize is 15s.; thus that sum is offered for three Cabbages, six Turnips, six Carrots, three Beets, three Cauliflowers, one Cucumber, six Tomatoes, one dish of Strawberries, one dish of Raspberries, nine Plums, and six Apricots. For Potatoes the first prizes are £1 for three varieties, nine tubers each, and 15s. for one variety of the same number of tubers.

— IT is asserted that in Paris no fewer than 30,000 women earn their living by the manufacture of ARTIFICIAL FLOWERS. The Rose is the test of proficiency which the workshops demand, whoever can counterfeit a Rose being supposed equal to the imitation of any flower whatever. In this, as in other branches of industry, there is usually a division of labour; the bud, the foliage, and the mounting being done by different persons. At present many flower-makers are out of work, owing in part to the competition of other countries, and in part to the fact that artificial flowers are not universally in fashion.

— THE Committee of the GARDENERS' ROYAL BENEVOLENT INSTITUTION have had under their consideration for some years past the question of augmenting the pensions by the sum of £4 each, but before this desirable object can be carried out they consider it necessary that the reserve fund should be raised to £20,000. For the last three years they have caused collecting cards to be issued among gardeners, nurserymen, and others interested in horticultural pursuits, and the result has been that the sum of £2400, including the "Arthur Veitch Memorial" fund has been subscribed. A further sum of £2250 is required before the Committee can recommend the proposed increase of the pensions. A gentleman, who for the present wishes his name withheld, has promised that if the sum of £1750 be raised before the end of the year he will give the munificent sum of £500 to complete the amount required. With a legacy of £500 and the sum of £150 at the bankers, only £1100 remains to be secured. Under these special circumstances the Committee take this opportunity of bringing the matter prominently before the subscribers, feeling assured that those who take an interest in the Institution will second, to the best of their ability, the exertions that are being made to alleviate the distress and minister to the comforts of old and deserving horticulturists. To the affluent and generous lovers of horticulture an appeal is made with confidence that it will be responded to, and gardeners are also appealed to in the hope that they will assist their poorer brethren. The Secretary will gratefully and thankfully acknowledge any contribution, no matter the amount, that may be sent to him at 14, Tavistock Row, London, W.C. He will also readily send forms to all who may apply for them with the object of aiding in this excellent work, which we commend earnestly to the attention of our readers. The sum of £1750 was distributed by the Institution in pensions last year.

— A CORRESPONDENT of "Vick's American Magazine" has the

following on *KALMIA LATIFOLIA*:—"Not only is this a most gorgeous affair when in bloom, but to witness a hillside dotted full of the trees when the ground is covered with snow and the sun shines brightly on part of the hill, and the rest is in the shadow, is something equally grand. I remember once standing on a knoll admiring such a scene, when the mercury was about zero, until my ears were about froze. It is, perhaps, the hardest wood we had in Pennsylvania, and I often wondered why it is not used for knife handles, &c."

— THE usual monthly meeting of the ROYAL METEOROLOGICAL SOCIETY was held on Wednesday evening, the 16th inst., at the Institution of Civil Engineers, 25, Great George Street, Mr. J. K. Laughton, M.A., F.R.A.S., Vice-President, in the chair. J. Y. Davidson and T. Wright were elected Fellows of the Society. The following papers were read:—1, "On the Origin and Course of the Squall which Capsized H.M.S. 'Eurydice' March 24th, 1878," by the Hon. Ralph Abercromby, F.R.Met.Soc. 2, "Waterspouts and their Formation," by Capt. J. W. C. Martyr. 3, "The Weather Forecasts for October, November, and December, 1883," by C. E. Peek, M.A., F.R.Met.Soc. This is a comparison of the weather indicated in the forecasts of the Meteorological Office with that actually experienced at Rousdon in Dorset. 4, "On Certain Effects which may have been Produced in the Atmosphere by Floating Particles of Volcanic Matter from the Eruptions of Krakatoa and Mount St. Augustin," by W. F. Stanley, F.R.Met.Soc. The author having obtained specimens of volcanic dust from Krakatoa, which was collected on board some vessels in the neighbourhood of the eruption, and having examined them under the microscope, is of opinion that such dust suspended in the atmosphere was quite capable of producing the recent remarkable sunrises and sunsets and other effects.

— THE first part of the "ILLUSTRATED DICTIONARY OF GARDENING" (170, Strand) is now to hand, and if it is a fair sample of the general character the work will be both a full and useful one when completed. The genera are arranged as in Paxton's and Johnson's Dictionaries, but brief descriptions are given with all the species named; and in the case of popular plants like *Achimenes* the best varieties are also described. Under each genus an outline of the culture and propagation is given, and many illustrations accompany the text. There is one remarkable defect, which in a popular dictionary is inexcusable—namely, neither the genera nor specific names are accentuated. Another misleading defect is that with the majority of the specific names the translation is given but in a few instances, apparently following "Johnson's Gardeners' Dictionary," some other character is given after the specific names, as in *Abroma angusta* (smooth-stalked) and *A. fastuosa* (prickly-stalked). Many synonyms are given, but the authorities are omitted. With these few exceptions the work appears to have been very carefully edited, the names and descriptions being accurate. The work is clearly printed, the names in bold type, the paper and engravings being also of good quality.

VIOLETS.

I HAVE read with interest the account "Viola" gives in your issue of Thursday, April 10th, on the successful frame culture of that winter favourite, the sweet-scented, ever-welcome Violet; but I should be still more pleased to be put in the way of a successful open-air treatment, or to be corroborated in an opinion to which I am reluctantly giving way, that the climate of North Lancashire is too rugged and cold to allow them to bloom in any profusion. Frames with me are not available, and having tried them in a lean-to orchard house in a 2-feet border against the wall, but totally without success, two seasons ago, I removed some of the crowns and placed them outside in a sheltered situation under a wall, open only to the south and west. They were planted in good leaf mould, and during the summer the exuberant runners were pulled off. When blossoming time came I looked in vain for satisfactory results, but even with the protection of bellglasses there were no blooms worth the gathering, and last season, although extremely mild, there was none.

The garden is situated on a gentle slope to the south, is well drained, and grows good kitchen produce and flowers. Should it be the cold damp of the climate, why should they not have flourished in the orchard house, the temperature ranging from 45° to 55° after Christmas? If any of your many correspondents can enlighten me I should be much obliged.—E. P.

NOTES ON ORCHIDS.

PRUNING *DENDROBIUM NOBILE*.—I am afraid some of your correspondents will think me rather discourteous in not replying to their questions before now, but I have been prevented seeing the Journal for a week or two. Some of your correspondents doubt my remarks about the young growths starting from the

base of the old pseudo-bulbs that had been taken away. What I call the old pseudo-bulbs are those that have bloomed, and as those that make an early growth bloom on that growth the following spring, it is from the base of these that the young growths start. Some of my plants that flowered early have now made growths from a foot to 18 inches long. These will have finished their growths in June, and will be well ripened by autumn when they are put to rest. Plants that bloom late, say May or June, have not time to make their growths early enough to get them ripened, hence they do not bloom till the growths are two years old. In this way they lose their foliage the next summer after the growths are made, and when in bloom have no foliage. With me all my early-flowering plants have foliage on the growths when in bloom as green as when growing in the summer. I send a growth about 3 feet long, but I have taken the blooms off, as I wanted them to send away. If the pseudo-bulbs are two years old before they bloom then they do not send up growths from their base when taken away, as there will then be some one-year-old growths on the plants, and from the base of the one-year-old pseudo-bulbs the young growths start. All who have seen my Dendrobiums are astonished at their vigour. I was talking to a gardener a few days ago who called to see me about cutting down the Dendrobium nobile, and he made the remark that he should have been afraid of killing his plants if he treated them as I do mine.—B.

[The pseudo-bulb sent is an exceedingly fine one. It is 2 feet 9 inches long, and to the tip of the leaves is 2 feet 11 inches long. The leaves are $1\frac{1}{2}$ inch in diameter, and the stem at the flowering part is 2 inches in circumference. We have never seen a more healthy and robust pseudo-bulb produced under any system of culture].

CALANTHE DISCOLOR.—This pretty species has been known in cultivation for over forty years, but has been rather scarce in England, though it appears to have been better known in Holland, whence the first plants sent to this country were obtained. The leaves are similar to but much smaller than *C. veratrifolia*; and the flowers, which are about an inch in diameter, are borne in a neat spike, have narrow deep purplish-brown sepals and petals, and a white three-lobed lip with the central lobe deeply cut. In reference to this plant Messrs. Hooper and Co., Covent Garden, write as follows:—

Fig. 78.—*Calanthe discolor*.

and is presumably nearly or quite hardy. The sepals are rich brown, and the labellum white strongly stained with crimson. A small block carefully prepared from a native drawing is sent herewith."

LISSOCHILUS GIGANTEUS AT HOME.—In a work recently published entitled "The River Congo from its Mouth to Bôlôbô," by Mr. H. H. Johnson, F.Z.S., occurs an interesting reference to *Lissochilus giganteus*, which is here reproduced:—"A splendid Orchid that shoots up often to the height of 6 feet from the ground, bearing such a head of red-mauve golden-centred blossoms as scarcely any flower in the world can equal for beauty and delicacy of form. These Orchids, with their light green spear-like leaves and their tall swaying flower stalks, grow in groups of forty or fifty together, often reflected in the shallow pools of stagnant water round their bases, and filling the foreground of the high purple-green forest with a blaze of tender peach-like colour, upon which no European could gaze unmoved."

ORCHID SALES.—At Messrs. Protheroe & Morris's rooms in Cheapside on Friday last a large number of imported plants of *Cattleya Eldorado*, *Cypripedium barbatum*, *Saccolabium giganteum*, *Oncidium cucullatum*, *Epidendrum prismatocarpum*, and other Orchids were offered for sale in good condition, but mostly realised moderate prices. In addition, several handsome varie-

ties of *Odontoglossum Alexandræ* and *Wilckeanum* were included, and for these the competition was very keen. One beautiful hybrid of the *O. Alexandræ* type or approaching *O. Wilckeanum*, with yellow ground flowers spotted with bright red, was sold for 19 guineas. Another of the *O. Ruckerianum* type, exceedingly beautiful and one of the most distinct varieties yet produced, with sepals deep purplish-crimson on the back, the whole flower also flushed with the same colour, the sepals and petals thickly dotted with rich crimson on the upper surface, and having a well-defined yellow margin. This magnificent variety, which was the centre of attraction, was sold for 21 guineas. A striking form of *O. Wilckeanum* with ivory-white flowers and very large spots realised $7\frac{1}{2}$ guineas, and others proportionate prices. Some of the less important plants were sold at very moderate prices; for instance, a good *Cypripedium niveum* and *Oncidium concolor* were sold for 15s. the pair.

ROYAL HORTICULTURAL SOCIETY.

APRIL 22ND.

THOUGH confined to a limited space in consequence of the National Auricula Society's Show, the groups of plants and flowers were very attractive, especially the Roses, Rhododendrons, and Daffodils. Probably, however, the most generally admired group was the grand collection of Mignonette from Mr. Warren, which was of a quality rarely seen at exhibitions. Several new plants and Orchids imparted additional interest to the meeting, which was extremely well attended by visitors.

FRUIT COMMITTEE.—The duties of this Committee were exceedingly light, and limited to the consideration of a few Apples. Mr. R. Gilbert, Burghley Gardens, Stamford, sent specimen of a Cabbage Broccoli, with compact white heads, which is to be tried at Chiswick. Mr. R. Dean, gardener to G. Leveson Gower, Esq., Titsey Park, Surrey, had a collection of nine dishes of Apples, comprising Reinette du Canada, Cox's Orange Pippin, Braddick's Nonpareil, Brickley Seedling, Court Pendu Plat, Winter Queening, Winter Pearmain, Sturmer Pippin, and Cornish Aromatic in excellent condition. A vote of thanks was accorded. Mr. Divers, Wierton Gardens, near Maidstone, showed a collection of twelve dishes of Apples in good condition, and a bronze medal was awarded for them. First class certificate was awarded for

Apple High Canons (Mr. Thrower, High Canons, Shenley, Herts).—A solid heavy Apple of good flavour, and evidently an excellent keeper. The fruits sent were 2 to 3 inches wide, slightly angular, with a deep open eye and short stalk. Its colour is a clean yellow, with a few streaks of crimson on the side to the sun.

FLORAL COMMITTEE.—Section A.—Mr. E. Hill in the chair. Present:—Messrs. J. O'Brien, H. Ballantyne, H. Williams, H. Herbst, J. Woodbridge, F. R. Kinghorn, and Rev. G. Henslow. Section B.—Mr. Shirley Hibberd in the chair. Present:—Messrs. W. B. Kellock, H. Bennett, G. F. Wilson, W. Bealby, J. Child, D. C. Lathbury, G. Duffield, H. Cannell, H. Eckford, and J. T. D. Llewelyn. Messrs. Veitch & Sons, Chelsea, exhibited a choice collection of new plants, including several good Azaleas and Amaryllises. Six boxes of *Narcissus bicolor* Empress and *lorifolius* Emperor were handsome. Mr. W. Warren, Worton Gardens, Isleworth, exhibited a group of extraordinarily fine Mignonette of the variety *pyramidalis grandiflora*. Seven or eight plants were placed in each pot, and formed dense compact specimens 8 or 9 inches high, with heads of flowers $1\frac{1}{2}$ or $1\frac{3}{4}$ inch in diameter, and 3 to 5 inches high, with prominent reddish anthers and white petals. The fragrance was extremely powerful, and altogether it was one of the finest samples of Mignonette that has ever been shown. A bronze Banksian medal was awarded for this.

Messrs. J. Carter & Co., High Holborn, contributed a group of Cinerarias comprising a great diversity of colours, both self and parti-coloured flowers being of good form and size. The strain is evidently a very good one, the colours being rich and decided, delicate, or pure white. They formed a bright group. A bronze medal was awarded. Mr. J. Geggie, Bury, Lancashire, sent a pretty group of seedling Primulas, varieties from P. Sieboldi representing diverse shades of rose, purple, and lilac. Some were prettily fimbriated on the margin of the petals, and all were flowering profusely. Sir Trevor Lawrence, Bart., Burford Lodge, Dorking, sent several Orchids, three of which were certificated. The fourth was a good specimen of *Cypripedium naviu* with large flowers densely dotted with small purple dots. Mr. G. Stevens, Putney, showed a group of Abutilons, including several good varieties, Lustrous with dark scarlet flowers being very noticeable; Miss Nicholls, pink, and Princess of Wales, deep rose, were the best. Mr. R. Aldous, gardener to G. Heriot, Esq., Lilford House, Cholmondeley Park, Highgate, had a fine plant of *Phalænopsis casta*, with handsome flowers $3\frac{1}{2}$ inches across, the petals rounded, the lip marked with crimson at the base. A vote of thanks was accorded for it.

Mr. B. S. Williams, Upper Holloway, exhibited a group of new plants, including several new *Sarracenias*, a wonderfully strong *Epidendrum bicornutum*, with six fine growths and two spikes of flowers. An elegant cut-leaved *Grevillia* named *Manglesi* was included, and a plant of *Cœlogyne Parishii* with yellowish green flowers and a black-spotted lip. For the *Sarracenias*, which were in fine condition, a vote of thanks was accorded. A vote of thanks was accorded to Sir C. W. Strickland, Bart., Hildenley, Malton, for a healthy plant of *Cattleya citrina*, growing on cork bark and bearing two fine flowers. De Barry Crawshaw, Esq., Rosefield, Sevenoaks, was accorded a vote of thanks for a plant of *Odontoglossum hebraicum* with large flowers richly spotted with red, and a plant of *Cypripedium Robelinii*, something like *C. lævigatum*, but the flowers were not fully expanded. Mr. Wilson, gardener to H. M. Pollett, Esq., Fernside, Bickley, sent plants of *Odontoglossum Stuartianum* with fine flowers, yellow barred, and spotted with chocolate. *O. Ruckerianum* insigne is a charming variety, spotted with crimson and edged with yellow. *O. polyanthum* was also good with large clearly coloured flowers. Mr. A. J. Sanders, gardener to Viscountess Chewton, Bookham Lodge, Cobham, sent two plants of a double purple

Cineraria named Rosy Morn. Mr. E. Weatherill, North Finchley, exhibited four seedling Pelargoniums with large handsome flowers. They were of the decorative type, one named Alice having large flowers, white stained with crimson. Messrs. Cutbush & Son, Highgate, sent a plant of the pale purple-coloured Japanese Daphne named Gwenka. Mr. Black, Fulwood Park, Preston, was awarded a vote of thanks for a seedling Adiantum of the gracillimum type, very elegant and compact in habit. Votes of thanks and a cultural commendation were awarded to Mr. Slogrove, gardener to Mrs. Crawford, Gratton Cottage, Reigate, for a head of a fine single Zonal Pelargonium named Mrs. Crawford, with very large flowers, and for a bunch of flowers of Chrysanthemums.

First-class certificates were awarded for the following plants.

Angræcum fastuosum (Sir Trevor Lawrence).—A pretty dwarf species, about 3 inches high, with elliptical leaves 2 inches long, $1\frac{1}{2}$ across, with two spikes of three flowers, one from each side of the stem, the sepals and petals pure white, lanceolate, about 1 inch long, the lip being similar in form and the white spurs 2 to 3 inches long.

Odontoglossum cinnamomeum (Sir Trevor Lawrence).—A distinct variety, with flowers $1\frac{1}{2}$ inch across, yellow spotted, and barred with rich brown; the margins of sepals and petals slightly undulated.

Dendrobium Harveyanum (Sir Trevor Lawrence).—One of the racemose group, with neat golden-yellow flowers, the petals and lip deeply fringed, the sepals narrow, but without the fringe.

Odontoglossum vexillarium splendens (Williams).—One of the finest coloured varieties that has yet been obtained, the flowers large and of a rich rose tint, running right through the flower, except a white patch at the base. The plant shown was bearing three spikes of five flowers each.

Primula Sieboldi Brilliant (Geggie).—Rich rosy crimson, well-formed flowers in dense heads.

Primula Sieboldi Purity (Geggie).—Flowers of good size, pure white, in trusses of seven to twelve.

Syringa vulgaris fl.-pl. Lemoinei (V. Lemoine, Nancy).—A pretty variety, with neat double flowers of a pale mauve tint, in dense heads.

Tea Rose, Etendard de Jeanne d'Arc (Bennett).—Bloom of moderate size, very full and extremely beautiful in the bud stage; white, with a very faint bluish tint. Free, and of good habit. This was raised by M. Jules Margottin, and has been found to be a very free and early-flowering variety.

Highly attractive features of the Show were the fine collections of Roses exhibited respectively by Messrs. H. Lane & Son, nurserymen, Berkhamstead, and Messrs. Paul & Son, the Old Nurseries, Cheshunt. Messrs. Lane's group was composed of remarkably handsome and well-grown plants, the following being especially noticeable:—Celine Forestier; Glory of Waltham, a fine plant, bearing upwards of twenty blooms; Docteur Andry; Jeanne d'Arc, bearing at least thirty buds; and Marquise de Castellane. The same firm also showed a very fine and varied collection of Rhododendrons, the plants being dwarf, bushy and well covered with flower heads. A silver-gilt Banksian medal was awarded for them. The Roses shown by Messrs. Paul & Son were magnificent, the plants being, as is usual with such exhibits from this firm, very fine and well grown, and they certainly formed one of the most pleasing groups in the conservatory. The following were the most conspicuous varieties, being in very fine condition:—Comtesse Riza de Parc, Countess of Rosebery, Duke of Teck, Innocenti Pirola, Madame de Montcheauvean, Madame Eugène Verdier, Madame Victor Verdier, Madame Villermoz, Perfection de Montplaisir and Souvenir d'un Ami; many of the plants having upwards of twenty-five blooms. A silver-gilt Banksian medal was awarded for them.

Another extremely pretty and effective stand was that of Mr. Thos. Ware, Hale Nurseries, Tottenham, who sent a mixed collection of spring flowers, consisting of Daffodils, Irises, Freesia refracta alba, Primula denticulata, P. rosea, P. Sieboldi, and Fritillarias. These, being tastefully arranged, looked particularly bright and attractive.

Messrs. Barr & Son, King Street, Covent Garden, were represented by a very large and fine stand of Daffodils, which formed one of the most striking features of the miscellaneous exhibits. Conspicuous amongst them were the fine flowers of Narcissus bicolor maximus, Incomparabilis Leedsii, Barri conspicuus, bicolor Empress, Poeticus ornatus, and many others. A bank of flowers of Amaryllises, Anemones, Fritillarias and Triteleias considerably heightened the effect, and a silver-gilt Banksian medal was awarded.

A vote of thanks was accorded to Mr. Eckford for some handsome blooms of Pansy Crimson Gem, a richly coloured variety. From the Society's garden at Chiswick a large group of Primulas and Auriculas was contributed, which included some well-grown plants.

THE TURF RITTER.

PERMIT me to say a few words on a handy tool which will be found invaluable by those engaged in cutting turf for lawns. One man can cut as many turves with ease with this implement as three men can with the ordinary edging-iron. I had mine made of an old gig or carriage shaft reduced to the following dimensions:—Length, 5 feet 6 inches; girth at thick end, $5\frac{1}{2}$ inches, with a knife 9 inches from the point, facing the point. The knife is 5 or 6 inches long, with four holes in it for adjusting it to any depth. Any stiff blade will do, such as an old table knife. The shaft has a narrow hole the shape of the blade through it, with a narrow sheet-iron case put in it as a support to hinder the knife from cutting or splitting it. Then a pinhole is drilled through the shaft and plate, the knife is put in and pinned, the instrument is finished, and in good land you can cut as fast as you can walk by pushing it forward.—GEO. MURRAY, *West Ashby Manor Gardens, Porceastle.*

TOMATO SAUCE.

IN response to "D., Deal's," inquiry for a recipe of a really good Tomato sauce that will keep, I gladly give particulars of the excellent sauce made last autumn by Mrs. Luckhurst, which we have now in daily use, and which I have every reason to suppose will keep good for a couple of years; at any rate it may certainly be relied on from one autumn to

another. Badly made sauce is soon spoiled, and I have heard it remarked, "What a pity so delicious a sauce would not keep," and this, too, with all due gravity, as though the matter were beyond dispute. Surely I am a more privileged being than I supposed! for my better half not only makes the best Tomato sauce I have ever tasted, but equally good chutney, pickles, jam, and wine, all keeping good for a long time, and the wine gaining in excellence by keeping—a sure indication of its high quality.

Care is taken to select sound and ripe Tomatoes, which are put in an oven in a pan and sufficiently baked to extract the watery juice of which they contain so much. They are then strained and the juice thrown away. To a gallon of the pulp is added a quart of the best vinegar, a tablespoonful of mixed spice, cayenne pepper at discretion—some palates like more or less of it than others—four large Apples peeled and sliced, a dozen large Shallots, less or more at discretion, according to taste. It is then boiled gently for two hours and stirred frequently and thoroughly. It is then passed through a sieve, salt is added freely, the best guide as to quantity being individual taste; it is again put in the saucepan with a pint more vinegar, boiled briskly for ten minutes, and is then ready for bottling. See that the bottles are quite dry before putting in the sauce; use new tight-fitting corks, and seal the tops as they are put in. The size of the bottles is immaterial, the sauce keeping equally well in quantities of half a pint or two or three pints, nor does the sauce spoil when the larger bottles are opened if the cork is put in again carefully.

A careless person will fail in this, as in most other things. To the careful it is almost superfluous to say that close attention to each detail of this simple recipe renders success a certainty.—EDWARD LUCKHURST.

IN reply to the request of "D., Deal," (page 303) for a recipe of Tomato sauce, I have much pleasure in forwarding the enclosed, that will keep two years. I have also sent by parcels post a sample that was made in October, 1883.

Let Tomatoes be quite ripe; take out the green stems, then wipe them and put them on earthen dishes, and place in a warm oven; let them remain until perfectly soft; skin them and rub them through a sieve, putting the seeds away. Then to every two pounds weight of Tomatoes add one quart of white wine vinegar, one dozen capsicums, a quarter of a pound of garlic, and a quarter of a pound of Shallots, peel clean and slice as thin as possible; to this add one ounce of white pepper in powder, and salt to your taste. Boil all together till it becomes thick as cream, stirring it and skimming off the froth. When the Garlic is quite soft rub the whole through a sieve with a wooden spoon, then boil it over again, and if too thick add a little vinegar, and if not spiced you may add a little more white or cayenne pepper. Keep it in a cool dry place after it is bottled and well corked.—F. F., *Herts.*

[The sample sent is excellent, the different ingredients being agreeably blended; but we do not think it will "keep" long, indeed the greater portion of it vanished on first being placed on our table. It is, however, in a perfect state of preservation, and if allowed would apparently keep for any length of time.]

ORCHIDS AT PENTLAND HOUSE, LEE.

NEARLY every villa, suburban, and country garden can now boast of a large or small collection of these singularly beautiful plants. It is, however, not so much the desire of those who have limited space to acquire a large as a small and choice collection. In some instances cool Orchids, such as the many excellent forms of *Odontoglossums*, &c., that do not require so high a temperature in which to grow and flower them successfully, are sought after the most. Others, again, include in their small collections a few of the choicer species of *Cattleyas*, *Oncidium*s, *Dendrobium*s, and *Phalænopsis*, in addition to *Odontoglossums*. And who forming a collection would fail to include the latter? A similar collection to the above is being formed by K. Whyte, Esq., Pentland House, Lee. The collection of *Odontoglossums*, growing in a cool span-roof house, embraces some hundreds of such good species as *O. Alexandræ* (of which I saw at the time of my visit many excellent varieties in flower), *O. Rossi majus*, *O. Pescatorei*, and *O. nebulosum*. In the same house, too, I noted *Oncidium cucullatum*, very good; *O. sarcodes*, and *O. Marshallianum* carrying a fine raceme of flowers. In addition to these were well-grown and flowering plants of *Ada aurantiaca*, *Dendrobium Jamesianum*, *Sophranitis grandiflora*, *Cattleya citrina*, the latter thriving remarkably well on blocks of wood, and showing flower buds freely; *Masdevallia ignea*, and fine specimens of *Cælogyne cristata*. The whole of the plants in this house were in the best possible health, although from necessity closely packed together. Mr. Reece, the energetic gardener at Pentland House, is a thorough advocate for giving plenty of air and dispensing with fire heat as much as possible, and the sturdy appearance of the plants certainly testify to the soundness of his practice.

In another large span-roof house devoted to Orchids and specimen stove plants there were several good varieties in flower of *Cattleya Trianae* and *Mendelli*, *Vanda tricolor*, *Dendrobium Wardianum*, *Farmeri*, and *aggregatum*, also *Phalænopsis Schilleriana*, all in excellent health, and the various species true to name and in good variety. We have only enumerated the principal ones in flower at the time of our visit a few days ago as typical of the choice collection now in course of formation there. A system of "weeding out" the inferior varieties is constantly practised, and it is hoped by so doing to obtain the best possible forms of this interesting class of plants. It will not be out of place to add that not only are Orchids a special feature here, but also a collection of

choice stove and greenhouse plants, with which Mr. Reece won the silver cup presented to those who win the greatest number of prizes at the local show.—SUBURBANIST.

EARLY AURICULA SHOWS.

THE *Ipswich Journal* has recently been publishing extracts from its early numbers. I forward one, which may have some interest for Auricula growers. If there any earlier record of an Auricula show?

"1744. The annual Show of Ariculas (*sic*) (The Prize to be a Half-pint Silver Mug) will be at the House of Samuel Healey at the Half

contrasts strongly with the light central stripe. It is a handsome effective variety, and is especially useful for associating with the dark-coloured forms of the Leopoldi type.

NATIONAL AURICULA SOCIETY.

SOUTHERN SECTION.—APRIL 22ND.

IN the opinion of some of the most experienced Auricula growers this Exhibition was the best that has been yet held, both in numbers and quality. It is true that some of the southern collections showed the signs of age rather too markedly, and on the other hand several of the northern exhibits

Fig. 79.—AMARYLLIS ALCYONE.

Moon in Bury St. Edmunds, on Thursday the 19th of this instant, April, where all Lovers of Flowers are desired to dine with the Stewards at one o'clock.

LAWRENCE WRIGHT, }
THOMAS MONES, } Stewards."

—DUCKWING.

AMARYLLIS ALCYONE.

THE woodcut (fig. 79), shows another type of Amaryllis from Messrs. Veitch's collection, which like those previously given is representative of a group of varieties similarly marked, but differing in size and form of flower and depth of colour. The flower is well proportioned; the petals are broad, rounded, and rich, but delicate crimson in colour, which

were correspondingly undeveloped, in a few cases the flowers were scarcely expanded. All were, however, distinguished by a most vigorous health, which in a few extreme instances almost verged on coarseness, but with these exceptions the leading collections of flowers were of a most refined character, clean, the colours and paste well defined, and the general symmetry and substance most satisfactory—a convincing proof of the increasing interest taken in Auriculas was afforded by the increased number of exhibitors, chiefly amateurs, who contributed plants that had evidently been carefully tended, but which could not take rank with the productions of the veterans in Auricula culture.

The Show was held in the conservatory at South Kensington, and tables on both sides for one-half the length were fully occupied with the plants entered, the other portion of the building being filled with the groups and miscellaneous plants shown before the Floral Committee of the Royal Horticultural Society. These united attractions induced a large number of

visitors to assemble, and during the afternoon the conservatory was crowded with Fellows and visitors.

The most important class in the Show, and one in which the greatest interest centred, was that for twelve dissimilar Auriculas, as in addition to the liberal prizes provided by the Society, the Veitch Memorial medal and £5 was offered for the best collection from gentlemen's gardeners or amateurs. It was, however, provided that the usual prizes should be awarded to the unsuccessful exhibitors in the order of their merit. Six collections were entered, and the much-coveted medal was, after careful and lengthy consideration, awarded to the Rev. F. D. Horner, Lowfields, Burton-in-Lonsdale, Carnforth, for handsome specimens, fresh, healthy, and with most refined flowers. He well deserved his success, although Mr. J. Douglas proved a formidable opponent, and had his flowers been a little younger and fresher it is probable that Mr. Horner would not have gained his position so easily. The varieties represented were as follows:—Back row: Mrs. Douglas (Simonite), F. D. Horner (Simonite), Mars (Horner). Second row: Magpie (Horner), Colonel Taylor (Leigh), Mrs. Horner (Turner). Third row: Heroine (Horner), John Simonite (Walker), Monarch (Horner). Fourth row: Moonlight (Horner), G. Lightbody (Headley), and Miranda (Horner).

Following this, Mr. J. Douglas, gardener to F. Whitbourne, Esq., Great Gearies, Ilford, was adjudged the first position with handsome strong plants bearing fine heads of well-finished flowers. The varieties were:—Back row: George Lightbody (Headley), C. J. Perry (Turner), Jumbo (Douglas). Second row: Pizarro (Campbell), Frank Simonite (Simonite), Prince of Greens (Trail). Third row: Lancashire Hero (Lancashire), Blackbird (Spalding), Smiling Beauty (Heap). Fourth row: Conservative (Douglas), Colonel Taylor (Leigh), and Marmion (Douglas). These were very handsome, C. J. Perry having a truss of eleven and Smiling Beauty ten pips. Mr. E. Pohlman, Halifax, was second with good examples of Ringdove (Horner), Prince of Greens (Trail), and C. J. Perry (Turner) amongst others. Third Mr. C. Turner, Slough; and fourth Mr. W. Brockbank, Didsbury, Manchester.

For six dissimilar varieties there were five collections. The Rev. F. D. Horner secured the first honours with F. D. Horner (Simonite), Enchantress (Horner), Heroine (Horner), Luna (Horner), G. Lightbody (Horner), and Monarch (Horner). A pretty collection. Mr. J. Douglas was a very close second with sturdy plants. Mr. E. Pohlman was third; Mr. Brockbank fourth; Mr. Bateman, Kent's Bank, Grange-over-Sands, fifth; and Mr. W. Rowan, 36, Manor Street, Clapham, sixth. These were all close in merit, and each collection included good plants.

The collections of four varieties were good as usual. Mr. B. Simonite, Sheffield, took the lead with excellent plants of Heather Bell (Simonite), Samuel Barton (Simonite), Merlin (Simonite), and Acme (Reed). Mr. T. C. Henwood, Hamilton Road, Earley, Reading, was a close second with Beauty (Trail), Dr. Horner (Read), Gipsy (Mellor), and Prince of Greens (Trail). Mr. E. Shaw, Street Fold, Meston, Manchester, was third; the Rev. E. C. Fellowes, Wimpole Rectory, Royston, fourth; Mr. W. Bolton, Warrington, fifth; and T. H. Welton, Esq., Rectory Grove House, Clapham, sixth. This was a particularly strong class, no less than nine collections being staged, and so nearly equal were most of them that the Judges had no easy task in making the awards.

For pairs of dissimilar varieties the competition was keen. Mr. E. Henwood was first with G. Lightbody (Headley), and Mrs. Douglas (Simonite); Mr. Shaw was second with G. Lightbody (Headley), and C. J. Perry (Turner); Mr. Phillips third, Rev. Fellowes fourth, Mr. Simonite fifth, and Mr. Bolton sixth.

SINGLE SPECIMENS.—A very large number of plants were entered in the four classes for single specimens, thirty to fifty or more in each, and amongst so large number it was evidently not an easy matter to select the most meritorious. But there was more delay than the case warranted, and so much confusion occurred in placing the prize cards that mistakes were unavoidable. The following list is, however, as nearly accurate as possible under the circumstances:—

Green-edge.—Rev. F. D. Horner was first, second, and fourth with Prince of Greens (Trail), F. D. Horner (Simonite), and Kestrel (Horner); Mr. E. Pohlman third, fifth, and sixth, Colonel Taylor (Leigh) and Prince of Greens (Trail); Mr. J. Douglas seventh and eighth with Prince of Greens, and Rev. F. D. Horner (Simonite). *Grey-edged.*—Mr. W. Brockbank was first and sixth, G. Lightbody (Headley), Dr. Horner (Read); Mr. E. Shaw second and eighth, G. Lightbody (Headley) and Alexander Meiklejohn (Kaye); Rev. F. D. Horner third, fourth, fifth, and seventh, Irreproachable (Horner), Thetis (Horner), and G. Lightbody (Headley). *White-edged.*—Mr. Pohlman was first with Acme (Read); Rev. F. D. Horner second and fourth with Acme (Read) and Beeswing (Horner); Mr. J. Douglas third, fifth, seventh, and eighth with Conservative (Douglas) and Acme (Read). *Sels.*—The Rev. F. D. Horner was first, second, third, and fourth with Heroine (Horner), Kathleen (Horner), Blackbird (Horner); Mr. J. Douglas fifth and sixth with Topsy (Kaye) and a seedling; Mr. C. Turner seventh and eighth.

The class for fifty plants invariably makes a good display, and though only two collections were staged they comprised a hundred plants which it would not have been easy to surpass. Mr. J. Douglas won chief honours in this class with a magnificent collection, including some splendidly flowered plants with large trusses, many with ten or twelve pips. The foliage was extremely vigorous, and the general condition of the plants indicated most liberal treatment. Some of the most notable were Smiling Beauty (Heap), thirteen pips; Vulcan (Sims), twelve pips; Beauty (Trail), nine enormous pips; Frank (Simonite), twelve beautiful pips; C. J. Perry (Turner), twelve large even pips; Lancashire Hero (Lancashire), eleven pips; and many others might be named of similar merit. Mr. C. Turner took the second position with beautiful plants but slightly inferior to the Essex collection, and, like those, they were all in remarkably vigorous condition.

ALPINE AURICULAS.—A pretty display of these was provided, though the competition was not so keen as in the Show variety classes. For twelve dissimilar varieties Mr. C. Turner was adjudged the first prize with vigorous plants of Cygnet, Gem, Luna, Murillo, Purple Gem, Garnet, Comet, Miss Llewelyn, Aurora, Unique, and Mrs. Thompson, most of them being Slough seedlings. Mr. J. Douglas was a close second, staging fresh and freely flowered specimens of Mrs. Llewelyn (Turner), Mrs. Meiklejohn (Meiklejohn), Diadem (Gorton), Ada Hardwidge (Douglas), Dolly Varden (Turner),

Miss Cope (Douglas), and several seedlings. In the class for six plants Mr. Turner was also the principal prizetaker, having good plants of Troubadour, Lavinia, Comet, Rainbow, Bayard, and a seedling. Messrs. Douglas and the Rev. E. L. Fellowes followed.

SINGLE SPECIMEN.—These were fairly represented, but not in large numbers. *Gold Centre.*—Mr. C. Turner was first, third, fifth, and sixth with a seedling and Unique. Mr. J. Douglas was second and fourth with Placida, Sensation (Turner). *White or Cream Centre.*—Mr. C. Turner was first and second with Rainbow and Princess of Wales, and Mr. J. Douglas third, fourth, fifth, and sixth with Queen Victoria (Turner).

The premier Auricula was a plant of Trail's Prince of Greens in Mr. Pohlman's second-prize collection of twelve. The truss contained eight even beautifully formed pips, which was greatly admired by the growers, and the most experienced were of opinion that a finer plant had never been shown.

SEEDLING AURICULAS.—Prizes were offered in each of the sections of Auriculas for the best seedlings, and the numbers entered were even greater than usual. The following awards were made:—*Green-edged.*—First and second the Rev. F. D. Horner. *Grey-edged.*—First Rev. F. D. Horner; second Mr. J. Douglas. *White-edged.*—First and second Rev. F. D. Horner. *Sels.*—First and second Rev. F. D. Horner. *Alpine Gold Centres.*—First Mr. C. Turner; second Mr. J. Douglas. *White or Cream Centre.*—First and second Mr. C. Turner. *Polyanthuses, Black Ground.*—First and second Mr. Brockbank, and the same exhibitor was first in the Red Ground class. There was so much delay in placing the cards to these plants that we are unable to give the names of the varieties honoured.

POLYANTHUSES.—A comparatively small space was occupied by these plants, but they were profusely flowered; their elegant gold-laced flowers being very attractive in comparison with the rich green vigorous foliage. Mr. Brockbank was first with six specimens, having well-grown examples of Exile (Crownshaw), Prince Regent (Cox), Black Drummond (Brockbank), President (Hitton), and seedlings. Mr. Barlow followed with similar plants, Mr. Douglas was third, and Mr. R. Dean fourth. Mr. Barlow staged the best three plants, which comprised the varieties Cheshire Favourite (Sanders), Exile (Crownshaw), and John Bright (Barlow). The single specimens were not shown in large numbers. Mr. W. Brockbank was first, second, fourth, fifth, and sixth with John o'Gaunt (Brockbank) and seedlings; and the Rev. F. D. Horner was third with Cheshire Favourite (Sanders).

EXTRA CLASSES.—A class was provided for twelve dissimilar Fancy Auriculas, and in it two pretty collections were staged. Mr. J. Douglas was first with good plants of Lord Tennyson, Cygnet, Snowdon's Knight, Khartoum, Luilette, and a seedling. Some of these were very prettily marked, yellow being the predominating tint. Mr. S. Barlow, Stakehill House, Manchester, was second with healthy but smaller plants of good varieties. Mr. Douglas also had the finest twelve Fancy Polyanthuses, flowering most freely, and was followed by Mr. R. Dean with much smaller specimens.

Seven groups of Primulas in the class for twelve plants, six to be distinct species, and these formed a very interesting portion of the Exhibition. J. T. D. Llewelyn, Esq., Penllergare, Swansea, was adjudged first honours for a superb collection of well-grown floriferous plants, amongst the best being some pretty varieties of P. Sieboldi, P. sikkimensis, P. verticillata var. sinensis, P. japonica, and P. rosea. That charmingly free species P. obconica had over twelve fine trusses, and P. pulcherrima was similarly good. Mr. Douglas took the next position with P. Sieboldi and its varieties, very beautiful. P. obconica was also well shown in this collection. Messrs. Paul & Son, Cheshunt, followed, having smaller plants in very large pots, the surface of the soil being covered with large pieces of spar. P. denticulata purpurea, P. viscosa, P. Munroi, and P. farinosa.

The Luncheon.—Shortly after 2 P.M. the members of the Society and their friends, to the number of thirty or forty, assembled in one of the galleries and partook of luncheon. J. T. D. Llewelyn, Esq., presided, Mr. Shirley Hibberd taking the vice chair. The usual toasts were duly honoured, Mr. Gorton responding for the Judges, the Rev. F. D. Horner for the exhibitors, and Mr. Shirley Hibberd for the horticultural press. A hearty response to the toast of the health of the Chairman brought that portion of the proceedings to a close, but Mr. Llewelyn stated that before the meeting dispersed Mr. Dodwell wished to make a few remarks upon a subject affecting him, and desired the attention of the members.

Mr. Dodwell said he had to draw attention to a statement in the *Journal of Horticulture* of February 14th, by a writer who assumes the signature of "Fair Play," and that statement was that he (the speaker) must be considered quite a nurseryman. He was sorry from the bottom of his heart that he had to bring the question before the notice of their worthy Chairman, but as the statement had appeared in public he had no alternative. The only favour he could ask at the hands of those present was that they would determine the question altogether apart from the manner of its having been made, the persons making it, or the person inculpated, and to determine it solely upon its own merits. If in their judgment he had lost status as an amateur he declared he would make whatever recompense in his power for the sins he had committed in showing as an amateur. He submitted he was that day, as he ever had been, an amateur, saving only in the brief episode of his life when he was at Bradshaw Garden, Manchester, twenty-five years ago. He urged that the line of demarcation between an amateur and a dealer was clear and distinct in the fact that a dealer not only reared, but bought and sold plants as a means of profit, whilst an amateur does not obtain a solitary iota—not one fraction—or the lowest mite of the realm as the result of his labours. The dealer goes in primarily for profit, the amateur does not put that in the forefront; that was an accident that came in afterwards. This equally governed other pursuits where the terms "amateur" and "professional" come in. He had never made a solitary penny in all his life, either as the result of the work of his pen, or from the productions of his garden. All had been in one sense constant loss, and in another way a gain, for his sympathies had been enlarged, and he was made a better man than he was. In the latter sense it had been a great advantage to him; but from a pecuniary point of view, as the eminent accountants, Messrs. Quilter, Ball & Co., could prove (and which proof he was ready, if necessary, to afford) he had never made a penny. He left the matter in their hands. He well knew from whom the anonymous communications emanated. The writers had been invited, but

were conspicuous by their absence. He had referred to them in the plural, but they could be counted on the little finger. He knew all about them. They had disturbed friends of the Society, and the latter had lost support, but he hoped the outcome of the matter would be that their support would be regained.

The question was afterwards referred to the Committee of the Society to consider, the Chairman urging that he knew of no single instance in which the Society had been injured by Mr. Dodwell showing as he had done.

Mr. Hibberd thought that Mr. Dodwell had not strengthened his case by saying that he had not made any profit by his transactions, as nurserymen could often say the same thing. He thought it was desirable that the question of defining what should be considered a *bonâ fide* nurseryman or amateur would be better deferred to a future meeting for fuller consideration, and concluded by proposing Mr. Dodwell's health, which was received with loud cheers.

THE INSECT ENEMIES OF OUR GARDEN CROPS. THE LETTUCE.

OUR juvenile naturalists are well aware of the fact, that in the lack of Mulberry leaves the common silkworm may be fed upon those of the Lettuce, and this plant, as the gardener often experiences to his vexation, is decidedly a favourite with a number of caterpillars belonging to the Lepidopterous order. Like the Cabbage and its allies, the Lettuce offers a convenient aliment to those caterpillars that prefer to feed near the ground, and more or less hidden from view. The caterpillars that are foes to the Lettuce are nearly all of the moth tribe, but the ubiquitous caterpillar of the small white butterfly (*Pieris Rapæ*) may be occasionally observed upon its leaves in small parties.

There is the familiar caterpillar of the tiger moth (*Arctia caja*) which is well clothed in black and grey, and which our children greet as a "woolly bear," though in the olden time people spoke of it as one of the "palmerworms," because its hairy garb resembled, they thought, the attire of the wandering palmers. Feeding by the wayside, the caterpillar seeks out Chickweed and Docks, but often the moth will deposit eggs in gardens, where a variety of plants serve for food to the caterpillars. The Lettuce, however, has a special liability to attack, it seems. The tigrine markings of black, white, brown and scarlet suggested the common appellation for this showy moth, which it is justifiable to capture and kill if ever it trespasses on garden ground, for every female deposits a large number of eggs. It is on the wing during July, and the caterpillars hatch out during the autumn, but feed little until after hybernation. Should they escape molestation, they are most voracious in May and June, and as they feed generally on the outer leaves of the Lettuce they can be easily found and removed. Few birds will touch these caterpillars, doubtless deterred by their long hairs, and it would appear they also keep off parasitic enemies.

Then in the destructive genus *Mamestra*, to which belongs the abundant Cabbage moth (*M. Brassicæ*) there are several caterpillars that infest the Lettuce; that of the moth just mentioned is one of these, but then its diet is very various, so that it may be found upon a dozen or twenty species in the kitchen or flower garden beside. The pot-herb moth, also rather oddly called the "bright line brown eye," from some markings in the wings (*M. oleracea*), is sometimes nourished by Lettuce leaves, but it is a tolerable promiscuous feeder while a larva. A rather local insect, the white colon (*M. albicolor*), the natural food of which seems to be the species of *Chenopodium*, shows a liking for Lettuces in gardens, the caterpillar feeding up earlier than that of *M. Brassicæ*, of which we may notice a succession through the summer. All these caterpillars are similar in habit, and nearly resemble each other, with smooth velvety bodies of brown or a dull green, small heads that can be hidden partially under the second segment, which has a plate or shield. That of *M. oleracea* inclines to be subterranean in habit, burying itself close to the stem of the Lettuce during the day. This caterpillar, and in fact all those in the group, are best detected at night by means of a lantern. Applications are not of much use, but soot or lime are sprinkled round the roots by some persons, and some caterpillars may be thus destroyed.

Upon the leaves of the Lettuce throughout Britain, yet not abundantly most seasons, feed the caterpillars of the shark moth (*Cucullia umbratica*). While it is light they conceal themselves under prostrate or bent leaves, eating ravenously after dark. Like their brethren in the genus, they are showy, the head and legs black, the body very dark brown, with markings and warts of smoky brown, also some orange spots. It is usually observed in August. The chrysalis lies underground from autumn to the next season, as do those of the species previously described, and they may be looked after during the process of digging or of forking. Every gardener has, at one time or another, handled the grey yellow-lined caterpillar of the silver Y, or gamma moth (*Plusia gamma*) fig. 80; this is another enemy of the Lettuce, but seldom occurs upon it in any large number. In our islands it is as a species less notably injurious to

cultivated plants than it is upon the adjacent Continent, where gardens are frequently desolated by swarms of this insect. And to add only one more to the list of caterpillars that diminish our crops of Lettuces, it should be remembered that the fat grub, so called, of the yellow underwing moth (*Triphaena pronuba*) may lie at the roots in May and June, escaping notice until the plants are pulled up.

A member of a troublesome brotherhood of tiny flies seeks out the flower heads of the Lettuce, and the result of its visitations is a loss of a certain portion of the seed. The moist winters of recent years have, however, been somewhat unfavourable for this insect, at least I judge that is the reason we have had few complaints concerning it for some time past. This fly (*Anthomyia lactucæ*) is like the Onion fly in size and form (fig. 81), but decidedly darker, the sexes differing in colour. The general tint of the males is black, but the abdomen is greyish, and the thorax has some white streaks. In the females we see a tint of greyish brown, the head having a red streak. Passing the winter in the chrysalis state, the mature flies come forth from April to June, and their eggs being placed at the base of the flower stalk (as is supposed) the maggots eat the unripe seeds, and they can migrate from stalk to stalk until they have obtained sufficient food. These are footless, with pointed heads and broadened tails, in length about a third of an inch when full grown. Some of them then descend to the earth, by chance or intention, and remain buried during the cold season. But the majority appear to turn to pupæ in the heads, and these objects, or "shucks," as they are styled in some parts of England, are of course apt to occur amongst parcels of Lettuce seed. It should be freed from them by running it through a sieve, the meshes of which will stop the "shucks," or otherwise, when the seed is sown, the pupæ of the fly are placed in the earth, from which the insect will afterwards

Fig. 80.—Gamma Moth.

Fig. 81.—Lettuce Saw-fly.

emerge none the worse. The maggots become pupæ in or about September, but they should be searched for earlier in the season, and suspected Lettuce heads cut out promptly.

Then the Lettuce has its particular aphid. The species is all the more troublesome because it infests the roots of the plant, causing it to droop and languish, though seldom killing, unless the weather be very warm. This insect, *Pemphigus lactucæ*, is one of the very small aphides, but in its greenish yellow colour and general aspect it resembles the Plum aphid, only it is minus the honey tubes which offer such attraction to the ants that follow other aphides. It has been recently stated in these pages that diluted paraffin has been found to be an efficacious remedy, and not hurtful to the roots of the Lettuces; the safe proportion is about 1½ oz. to a gallon of water. Copious applications of strong soapsuds or tobacco water to the ground have also been serviceable. These things may serve also to destroy any of the wireworms or elaters, if such should be at the roots, and the partiality of these for the Lettuce is indicated by the fact that the leaves put amongst other plants answer as baits to attract them. Plenty of good manure is unfavourable to both aphid and wireworm.—ENTOMOLOGIST.

NARCISSUS TAZETTA VAR. FLORIBUNDUS.

Now that the Narcissi are engrossing so much attention from the horticultural public it may not be amiss to mention this fine variety, which has been growing in a semi-wild state for the past 200 years at St. Michael's Mount, near Penzance, Cornwall. This is one of the earliest, and so soon in the season as last Christmas I noticed several just commencing to flower. Its nomenclature was decided by Mr. F. W. Burbidge, to whom I sent a few plants some three or four years since. It would be interesting to know how they have succeeded in Ireland, and at what period of the year they flower there. It is during the three months of February, March, and April when the extensive colony at the afore-mentioned Cornish habitat is in its full beauty, the sight is then a very beautiful one. They grow and flourish exceedingly well within a few feet of the sea, thoroughly exposed to all weathers. As a matter of course the best effects are obtained by growing it in clumps. Considering *N. Tazetta* to be a south European plant, it is perhaps scarcely

surprising that the variety in question does so well in Cornwall.—
WILLIAM ROBERTS, *Peckham*.

VINE-GROWING AT CASTLE COCH.

At a recent meeting of the Cardiff Naturalists' Society, Mr. A. Pettigrew of the Cardiff Castle Gardens read a long paper upon some experiments in Vine culture out of doors which he had been for some time engaged in at Castle Coch. After referring to the history of the Vine as an outdoor fruit in this and other countries Mr. Pettigrew described his experience as follows:—

SITE OF THE VINEYARD.

It is now eleven years since my noble employer, the Marquis of Bute, told me he purposed planting a vineyard somewhere in the neighbourhood of Cardiff, on the French system, and named Castle Coch as being a most likely situation for trying the experiment. I was in Scotland at the time, and his lordship delayed definitely deciding till I had seen the proposed site and given my opinion of it, and of the suitability of the soil for growing Vines. I had at that time had no experience of the climate of South Wales, but I was pleased with the soil and the situation, and reported so to his lordship. The ground selected lies to the left of the Castle at a somewhat lower level, with a gentle slope to the south, and from the nature of the ground it requires no artificial drainage. It is protected from the north by a large plantation, which covers the breast and summit of the hill behind. It is also protected from the east and west by smaller hills at some little distance off, and lies quite open to the south, overlooking the Bristol Channel, which is four or five miles distant. The soil, which is 2 feet deep, is a light fibry loam resting on a broken limestone rock—just the kind of soil that Vines like to grow in. The plan proposed at first was to get an intelligent young man from some of the well-known vineyards in France to assist me in selecting the varieties and in planting the Vines, and perhaps to remain to dress the vineyard and make the wine. After some correspondence we learned that it would be extremely difficult to induce a person of the class wanted to leave his home and friends to come here on any consideration. I was accordingly instructed to go to France myself and visit the principal vineyards in the Medoc and elsewhere, and gain all the information I could. It was a rather perplexing duty to one totally unacquainted with the French language; but furnished with letters of introduction to wine merchants and the principal vineyard proprietors in France and others, I set out in the latter end of September in time to see the vintage of the year. After presenting my letters of introduction in Paris the principal of a large firm there kindly sent one of their men, who could speak a little English, with me for two days to show me the vineyards around Paris and other objects of interest. In visiting the vineyards my guide was at great pains to explain everything the vineyard proprietors told him respecting the different modes of culture. My practical experience of the Vine in this country enabled me readily to grasp the facts my teacher meant to convey. The general treatment of the Vine as practised in the small vineyards in the neighbourhood of Paris is somewhat different from the treatment they receive in the south of France, and quite different from the mode of Vine-growing followed in this country. Many of the small Vine proprietors cannot afford to keep a wine press for themselves; but every village in the wine district has a public press, the use of which can be had on payment of a small fee. Here the juice is extracted from the Grapes, run into barrels, and taken away and fermented at home. The small proprietors, as a rule, are an industrious hardworking class, who make the most of every inch of ground. The vineyards are neatly kept, and when young Vines are planted the spaces between them are filled with some other crop till the Vines are old enough to occupy all the ground.

THE CHAMPAGNE VINEYARDS.

After learning all I could in the vicinity of Paris I went to Chalons-sur-Marne, in the champagne country, with a letter of introduction to a gentleman of the name of Jacqueson, who was the proprietor of one of the largest champagne manufactories in France. Unfortunately, I learned on my arrival that he had gone to Paris, but his manager kindly showed me through their enormous cellars, which are cut in the chalk hills. Lines of rails are laid through the principal passages, and railway trucks are taken in and loaded and despatched to all parts direct from them. Openings are cut from the surface in several places in the cellars, and strong reflectors placed under them to give light. My guide informed me that they had a stock of five million bottles of champagne on hand. The treatment of the Vines here was much the same as that practised in the vineyards near Paris. M. Jacqueson, besides having a vineyard of his own, is a large buyer of Grapes from the Vine-growers in the district to make into champagne. The gentleman in Paris from whom I had the letter of introduction told me that M. Jacqueson's father was a Scotchman, and a great enthusiast in the culture of the Vine. He said that at one time he went to great expense in making straw mats to protect the Vines from the cold winds and chilling frosts in the early part of the season, with the idea of improving the crop and making a better class of wine, but the expense was so great that the scheme had to be abandoned.

BORDEAUX VINEYARDS.

I next visited Bordeaux, and delivered a letter I had to a large firm there, the head of which showed me great kindness. He placed one of his clerks at my disposal—a young Scotchman, who could speak French like a native—to introduce me to the managers of some vineyards in the Medoc, and to act as interpreter. We visited several vineyards, and I was fortunate in arriving in time to see the vintage of three of the principal chateaux in full operation. These were Chateaux Latour, Lafitte, and Margaux. Chateau Latour contains 103 acres, Lafitte 165 acres, and Margaux 197 acres. The conformation of the country here is that of a vast plain, with a gentle incline towards the river Gironde. The soil has to all appearance been covered by the sea at some time. The surface is sprinkled with small water-worn stones and sand, but the soil varies in places. The manager of one of the vineyards said that the variation of the soil caused a variation in the wine, so that in some places the best and most inferior wines grew side by side. As the Vines are the same variety and the culture identical, the soil alone can explain the differ-

ence. The vineyards are intersected by roads of just sufficient width to admit of a cart or wagon passing along conveniently without interfering with the Vines. These roads lead to the principal approach to the chateau where the Grapes are pressed. The Vines are planted in rows, about 3 feet apart each way, and the rows are as nearly at right angles to the roads as possible. When the vintage begins a cart with two half-hogsheads on it, drawn by two oxen, is taken to the section of Vines to be gathered. Women and children cut the bunches, and men carry the full baskets from the cutters and empty them into the half-hogsheads on the cart, and when they are full they are carted to the press-house, where they are converted into wine. The upper floor of the press-house at Chateau Lafitte is on a level with the top of the vats. The hogsheads are lifted from the yard below by machinery similar to that in use in granaries here, and the Grapes emptied on a boxed-in platform, containing a machine for separating the Grapes from the stalks. The berries pass through wire netting, and the stalks are thrown on one side. The platform runs on rails which encircle the whole set of vats. When the cart with the Grapes arrives the platform is run to the door, the hogsheads hooked on, raised, and emptied. The platform is then removed to the side of the vat which is being filled, and the Grapes passed through the machine and shovelled into the vat. The Grapes are not trodden with the feet here as I have seen done at some places I visited. When the vat is full a cover is put on, and it is hermetically sealed. A siphon is then introduced through the centre of the cover into the vat, and the other end of it placed in a tub of water, which allows the gas to escape, while the water in the tub prevents the air from coming into contact with the wine. After fermentation, which generally takes from four to five days in good seasons, though a great deal depends on the temperature and the state of the weather, the wine is drawn off and transferred to enormous barrels in the storehouse. When the wine has been all run off the pulp is put in the press and the juice extracted.

PLANTING THE VINES AT CASTLE COCH.

The vineyard at Castle Coch was planted in the spring of 1875, on the French system, as practised in the neighbourhood of Paris, Burgundy, and in the champagne country. The ground in the vineyard had been thoroughly trenched and levelled the previous winter. The Vines are planted in rows from north to south, 3 feet apart, and the plants are 3 feet apart in the rows, and trained to stakes 4 feet high, and pruned close to the ground every year. A great many varieties of Vines are grown in the vineyards of France, but some of the best varieties grown in the south do not succeed when planted in colder districts. I was strongly recommended by the Vine-growers in the vicinity of Paris to try the varieties I planted at Castle Coch (Gammy Noir and Mille Blanch) as being two of the varieties most likely to suit our climate. They are extensively grown about Paris, in Burgundy, and in the colder wine-producing districts of France. The plants have a strong constitution, they produce fruit freely, and make very good wine. We had three or four good seasons in succession after they were planted. They grew well and made strong canes, which ripened thoroughly. Gardeners and others who came from a distance to see the vineyard were surprised at the luxuriance of the Vines growing in the open air, and simply trained to stakes in the way that Raspberry plants are trained in this country. The sight about the end of July is a novel and interesting one. Long rows of Vines as straight as a line, in a curved slope down the hill, and the tops of the canes all neatly stopped at the height of 4 feet from the ground, with their large dark-green glossy foliage almost meeting in the rows, was a sight not to be seen anywhere else in this country. I was very well pleased with the progress the Vines made for the first three or four years. During these fine seasons the Vines on the Castle wall at Cardiff produced heavy crops of Grapes, which ripened well. Indeed, some of the bunches that were thinned were as good as the Grapes that are generally to be found at the *tables d'hôte* in France. Taking all things into consideration, I felt sanguine at this time that the experiment at Castle Coch would be a success in good seasons. The Vines were growing vigorously, and there were no signs of the dreaded phylloxera, so common in many places in this country now. The only pest that attacked them was a kind of fungus called "Oidium Tuckeri," which was soon got rid of by picking the affected leaves off and burning them.

PROGRESS OF THE VINES.

We made the first wine from the vineyard in 1877. The crop was not a heavy one, but sufficient to enable us to make about 40 gallons of wine. The Grapes were brought down from the vineyard to the gardens in Cardiff, and the berries separated from the stalks and crushed in a machine made for the purpose, and a little water added to the "must," which lay for twenty-four hours in a wooden vat before being put into the wine press. Three pounds of the best cane lump sugar were added to every gallon of liquor, and then it was all put into a barrel to ferment. Strong fermentation lasted for about twenty days, after which the bung was put in gently at first, and when fermentation had ceased altogether it was driven hard in. The wine was racked off several times during the following spring and summer, and it was finally bottled off after having lain for a little more than a year in the barrel.

In 1878 the crop of Grapes was better, but still far from being a full crop. The Vines were, however, gaining strength, and I expected to get a full crop soon, if the season kept favourable. The Vines broke well in 1879, and showed an abundance of fruit in the latter end of May, but with the cold and sunless wet summer that followed the fruit all dropped off, and we did not gather a bunch of Grapes from the vineyard. This was not much to be wondered at in a season in which farmers could not get their corn to ripen. In passing I may say with respect to the cultivation of the Vine, that one bad season in which Grapes will not ripen means two bad seasons in succession. If the Grapes will not ripen the wood will not ripen either, and it is upon well-ripened wood that a crop of Grapes, or any other kind of fruit mainly depends. The vineyard was a failure in 1880 on account of the wood not being ripened in the previous season. There was a very good crop in 1881, but I have not been able to make wine since, owing to the bad seasons that have followed in succession. The Grapes on the Castle wall at Cardiff have failed to ripen their fruit during this period. They show plenty of fruit, but the bunches get eaten up with mildew long before they are ripe.

To sum up briefly, the really experimental time for the vineyard at Castle Coch has been the worst we could have had for the last twenty or thirty years, and the results to be observed from the trial as yet cannot be pro-

nounced satisfactory. There is nothing in the conditions of the soil or climate to hinder the healthy growth of the Vines, but the absence of sun heat has prevented the development or ripening of the fruit. It has yet to be proved whether in a succession of ordinary good seasons a better result will be arrived at. I am myself hopeful that it may be; and that it may yet be found that the outdoor cultivation of the Vine may be prosecuted in favourable situations in this country (at least on walls and gables of houses) with not much greater risk of failure than in the case of ordinary garden fruits.

BEDDING HYACINTHS AND TULIPS.

HYACINTHS and Tulips are now grown so extensively, and their successful cultivation is so well understood for bedding out, that it is a difficult task to particularise instances where superior culture and choice of varieties demand special notice. I was, however, agreeably surprised to see in the gardens of Pentland House, Lee, a number of circular beds filled with that good-sized red variety of Hyacinth, Robert Steiger; the blue Baron Von Thuyl, also a single variety; and the Pottebakker white and vermilion-scarlet Tulips. The varieties were massed in separate beds, and the spikes of the Hyacinths were wonderfully strong, and the individual flowers large and striking in colour, as were also the Tulips. White Pottebakker is an excellent white for bedding, and a better choice of scarlet could not have been made than in selecting Vermillon Brilliant. I have seen and proved a vast number of other named varieties of Hyacinths and Tulips for bedding, but find the subjects of this note to be the best for the purpose. Mr. Reece, the gardener there, is an enthusiastic cultivator of the Hyacinth and Tulip both in pots and bedding out, and is certainly to be congratulated on the very effective display he has made and the general excellency of their culture.—SUBURBANIST.

ROYAL BOTANIC SOCIETY.

APRIL 23RD.

THE second spring Show of the season was well attended by exhibitors, but the greater portion of the display was furnished by nurserymen and non-competing amateurs. In the corridor the exhibits were much better arranged than at the previous Show, a broad table on each side being devoted to the plants in place of the central one, upon which they could not be seen to good advantage. The conservatory also contained several fine groups.

Stove and Greenhouse Plants.—A pretty bank was formed by the four collections entered in the class for twelve plants in 12-inch pots, all being of moderate size, healthy, and in several cases well flowered. Mr. H. James, Lower Norwood, was first with some beautiful Azaleas, Ixoras, Epacris, Eriacas, a good Anthurium Schertzerianum, and neat Francisca confertifolia. Mr. G. Wheeler, gardener to Lady Louisa Goldsmid, St. John's Lodge, Regent's Park, followed with a most creditable collection, his specimen of Hibbertia Reedi being in beautiful condition, Adenandra fragrans and Azalea Stella being similarly good. Mr. R. Butler, gardener to H. H. Gibbs, Esq., St. Dunstan's Lodge, Regent's Park, was third with rather irregular plants.

Azaleas.—Mr. C. Turner, Slough, had the best six plants in the nurserymen's class, pyramidal specimens of Duc de Nassau and Mons. Thibaut being loaded with large flowers. Mr. H. James was second, his best plant being punctata maculata, of conical form, profusely flowered. Mr. Wheeler staged the leading amateurs' six, rather loose, but well-flowered plants, followed by Mr. H. Eason, gardener to B. Noakes, Esq., Hope Cottage, Highgate, and Mr. R. Butler, both showing plants of poor quality.

Roses.—One side of the corridor was devoted to Roses in the classes or otherwise, and these constituted one of the most beautiful and imposing features of the Exhibition. Both large and small plants were in admirable health and flowering abundantly. The best amateurs' six plants were staged by Mr. Perry, gardener to W. G. Rowlett, Esq., The Woodlands, Cheshunt, small but vigorous, with well-developed foliage and flowers. Mr. Wiggins, gardener to W. Clay, Esq., Kingston, took the second place with smaller but clean examples. Messrs. Paul & Son, Cheshunt, secured the leading place with nine plants, superbly grown specimens, 3 to 4 feet high and as much in diameter. Especially fine were Magna Charta, La France, and Madame de St. Joseph. Mr. Rumsey, Waltham Cross, was second with much smaller plants, but some had very large blooms.

Messrs. Wm. Paul & Son, Waltham Cross, contributed a magnificent group of Roses, both in pots and cut flowers; of the latter six boxes were staged. A few Clematises were also arranged with them and improved the effect. A silver-gilt medal was awarded. A large silver medal was awarded to Messrs. Paul & Son, Cheshunt, for an extensive and attractive group of Roses in pots, mostly specimens of moderate size and bearing large blooms. A large silver medal was also awarded to Messrs. Lane & Son for a good collection of about two dozen Roses in pots.

Messrs. H. Lane & Son, Great Berkhamstead, had the only collection of twelve Azalea mollis in the nurserymen's class, and were awarded the first prize for fairly well-flowered plants of buff, salmon, and reddish-coloured varieties. Messrs. H. Lane also won first honours with twelve Rhododendrons, large tree-like specimens, bearing enormous trusses of flowers. The variety Baroness Rothschild was especially notable for the brilliant crimson-scarlet colour of the neat flowers.

Auriculas.—Three collections of twelve plants were entered, Mr. J. Douglas taking first honours with strong plants of Pizarro (Campbell). George Lightbody (Headley), Smiling Beauty (Heap), Frank Simonite (Simonite), Mabel (Douglas), Conservative (Douglas), Jumbo (Douglas), C. J. Perry (Turner), Prince of Greens (Traill), Lord Clyde (Campbell), Marmion (Douglas), and Lancashire Hero (Lancashire). Mr. E. Pohlman, Parkinson House, Hereford, was second, and Mr. C. Turner third.

Mr. C. Turner secured first honours with nine Pelargoniums, well-grown plants with large flowers; Mr. J. Hill, The Gardens, Hillingdon Place, being second with small plants. Mr. James had the best nine Anemones of his usual good quality, followed by Mr. Hill and Mr. Todman, Upper Tooting. Two fair collections of twelve Amaryllises were entered by Mr. J. Hill

and Mr. R. Butler, who were first and second respectively, the flowers in both being small but brightly coloured.

A small silver medal was awarded to Messrs. Barr & Son, Covent Garden, for a large collection of Daffodils and hardy flowers tastefully arranged. A large bronze medal to Messrs. Carter & Co., High Holborn, for a group of Cinerarias. A similar award was made to Mr. Wiggins for a group of Cinerarias. A large bronze medal was adjudged to Messrs. Cutbush and Son, Highgate, for an interesting collection of greenhouse plants. A large silver medal was awarded to Mr. B. S. Williams, Upper Holloway, for a handsome group of choice Orchids and other plants.

A large silver medal was awarded for a large and fine group of Rhododendrons in pots, shown by Messrs. H. Lane & Son, The Nurseries, Berkhamstead. A large silver medal was awarded to Messrs. Paul & Son, Cheshunt, for a group of standard Roses in pots, which made an excellent display. A large silver medal was awarded to Mr. Wm. Rumsey, Joyning's Nurseries, Waltham Cross, for a splendid collection of about fifty dwarf Roses in pots, together with five large boxes of cut blooms: this group was exceedingly handsome and attractive. Mr. Charles Turner, Slough, exhibited an excellent collection of Show and Alpine Auriculas, for which a small silver medal was awarded. Messrs. James Carter & Co., seedsmen, High Holborn, showed a collection of their well-known Empress Poppy Anemone and Cockade Ranunculus, also a basket of Cloth of Gold Primrose.

KITCHEN GARDEN.

Thinning out Young Vegetables.—Parsnips, Carrots, Onions, Beetroot, Lettuce, and every vegetable which is sown in rows or beds grow fast at this season, and where the seed has been put in thickly the young plants soon become crowded. So much is this the case in many instances that by the time the plants are 2 or 3 inches high they have become a close mass, and they are drawn up and grow weakly in consequence of this. All young vegetables crowded in the seed beds show the injurious result of it for a long time afterwards, and many of them never fairly recover. If crops, no matter what they may be, are to be grown to the highest state of perfection crowding must never occur, and our readers would do well to bear this in mind at the present time. Some of the young plants should be drawn out as soon as possible, and by the time any crop is 3 inches high the plants should be 3 inches apart from each other. This is the preliminary thinning, and as growth advances it must be carried out farther; 6 inches apart is not too much for Carrots, and Parsnips should have double that space. Turnips are apt to become crowded before we know that they have begun to grow much, as they run up so fast, and they should be thinned out to 8 or 10 inches apart. Some growers do not thin their Onions, but they sow thinly, and where they come up in crowds some of them should be drawn out. In fact, wherever it is seen that the young plants are growing too closely and becoming matted thin them out as soon as possible.

Transplanting.—Lettuces, Cabbages, early Brussels Sprouts, &c., which have been raised from seed sown this spring should now be transplanted to their proper quarters. It is a great advantage to do this during showery weather, but when this does not occur it is better to attend to the transplanting rather than allow the plants to be spoiled in the nursery beds. When each can be lifted with a small ball of soil attached to the roots and planted with this entire they will not experience any check, and they will grow away freely. Should dry weather continue long after planting they should be watered until growth has fairly commenced, and the roots are penetrating the soil.

Mustard and Cress.—A constant supply may be kept up by sowing a patch of seed every fortnight. This may be placed in any corner, and the seed should merely be strewn on the surface of the soil, beaten down with the back of a spade, and watered if too dry.

Beetroot.—The main crop of this should be sown now. Dell's variety will always give satisfaction. The rows should be 15 inches apart and 2 inches deep. The soil must be free and open, and only moderately rich. As a rule growers are apt to sow too much Beet, and we have decreased our stock from time to time until we find that a few rows will supply the pantry for a very long time. Last year we had most of our Beet in the flower garden, as the leaves of Dell's are most effective, and may be used in a pleasing way in many combinations.

Kohl Rabi.—At one time this was supposed to become a substitute for Cabbage, Turnips, and many other vegetables, but in reality it possesses very little merit, and those who would like to grow it should not do so too extensively or they may be disappointed. It may be sown in a bed and transplanted when 4 or 5 inches high.

Spinach.—Sow the round-seed sort fortnightly in cool rich soil; seed put in now will produce a supply by June, and as it is not long in running to flower, from then onwards sow small quantities often until the end of July.

Celery Trenches.—These may now be made and manured ready for the first crops. If made 15 or 18 inches wide they will hold two rows, and this is a very convenient way of growing it. The trenches should be from 9 inches to 1 foot in depth, and the manure which is put into them

should be both plentiful and good. Between every two trenches there will be a space or ridge of soil 18 inches or more in width, and if Lettuces are planted on the apex of these they will be matured and cut before the Celery requires to be earthed up. Spinach, Turnips, or any quick-growing crops may also be put on these ridges.

Runner Beans.—The first row of these may now be sown. Sutton's Giant White is a splendid variety. It is large in pod, prolific, and finely flavoured. A sunny position will forward them and agree with them well, as this crop is a tender one and requires a little extra attention early in the season. A cold soil will not suit the seed, as the plants will be weak and chilled-looking in such. When the soil is light and dry they are much better. The drill for the reception of the seed should be 2 inches deep and 9 inches wide. Sow thinly and cover with some light sandy soil.

Tomatoes under Glass.—These must be restricted, and when a good crop of fruit has been formed stop all growths, and the fruits will swell off all the better for it. Do not give young plants liquid manure yet, but supply it freely to those in full bearing. Plants intended for open-air culture should be hardened off by being placed in cold frames before April is out, and in a fortnight hence they should be placed in the open in a sheltered position previous to being planted out.

Vegetable Marrows and Gourds should be treated in the same way.

FRUIT-FORCING.

Figs.—Earliest Forced Trees.—Figs started in November are now ripening, and to have them really good in quality considerable attention must be given to the house and trees, especially if the weather be cold and sunless. To secure colour the trees must have full exposure to light, and the means of admitting air freely with heat sufficient to allow of its being given in the coldest weather to prevent the condensation of moisture beneath the glass. In the treatment of the trees now remove all useless spray, thinning and stopping side shoots, and turning aside any leaves likely to shade the fruit. Although Figs require dry heat when ripening it must be borne in mind that the Fig is a gross feeder, and the roots require to be kept in a moist state through all stages, and this is best secured by mulching heavily with short manure or other non-conducting material after well soaking it with tepid liquid manure. The syringe, though it must not be used over the trees when the fruit is advanced in ripening, must not be entirely laid aside, as each time the ripe fruit is closely gathered a good washing with tepid soft water will greatly refresh the foliage and wood, and keep down red spider. The temperature may be now kept at 65° to 70°, and 10° to 15° higher by day from fire heat, and with bright sun 85° to 90°. Allow a circulation of air through the house constantly.

Succession Houses.—Generous treatment will now be necessary in the supply of heat, moisture, and syringing twice a day. Stimulants in the form of liquid manure should be given when the trees require it. Keep all stopping and tying well in advance, and thin the crop where too heavy, as the fruit will not be fine with too heavy a crop, but the trees are often seriously injured. Most trees show, when in good condition, far more fruit than they are able to bring to maturity, and if the border becomes dry the trees will shed the whole of their fruit.

Cherry House.—The fruit is now ripening rapidly; indeed, some of the most forward are fit to gather, and the fruit, whether ripe or ripening, must be kept free from moisture or it will crack and be entirely spoiled. The house, however, may be damped twice a day to maintain the health of the trees, leaving a little air on constantly at the top of the house to prevent moisture condensing so as to injure the fruit. Ventilate freely at all times under favourable external conditions, and when practicable allow a constant circulation of air through the house, and when the external conditions render this impracticable recourse must be had to the heating apparatus so as to ensure a circulation of warm and dry air. If black aphides appear they must be promptly exterminated by dipping the shoots or leaves affected in tobacco water, and rubbing them gently with the finger. Some netting will be needed over the ventilators to save the ripening fruit from the depredations of birds. As the shoots required for extension or filling up vacant space lengthen, tie in, but not too tightly, or it may produce gum, and stop those required for forming spurs at the fifth or sixth leaf. See that there is no deficiency of moisture at the roots, and trees in pots will need frequent attention.

PEACHES AND NECTARINES.—Early Houses.—Trees in houses where the fruit is swelling should, to ensure it reaching a good size, and especially where time has been lost in the stoning process, be closed early on fine afternoons with liberal moisture, syringing the trees in the morning and again after closing at 2 to 3 P.M. It is essential that the fruit become dry before night, for water lodging thereon for any length of time will cause the skin to crack, and it is then spoiled both in appearance and flavour. Examine the inside borders, and on no account allow the soil to become dry, and with the large spread of foliage exposed to the action of the sun the strain upon the roots is considerable, and will need copious supplies of tepid liquid manure and mulchings, partly decayed manure being most suitable. Too much stress cannot be laid upon this, as from a deficiency of moisture at the roots premature ripening and loss of the fruit before it has completed its last swelling is to be attributed; always taking into consideration the crop, as the fruit may not mature properly from an over-crop, or from a deficiency of water. Stopping beyond the fruit must have attention, and tying down so as to admit all the light practicable to the fruit, which should have any leaves turned aside or shortened, so that it receive the full benefit of the solar rays. Any dependant fruit should be raised and turned round to the light, so that its apex may be uppermost, supporting it in that position by thin laths fixed across the wires of the trellis.

Succession Houses.—Trees in the house started early in the year will have finished stoning, and when this is completed the treatment may be the same as advised above for early houses, with the addition of giving the fruit the final thinning. On trees in the house started at the beginning of February the fruit will not swell much during the stoning process and must not be kept too warm. Provide a night temperature of 60°, falling to 55° through the night, and keep at 60° to 65° from fire heat through the day, advancing to 75° from sun heat, ventilating from 65°, fully at 75°; do not allow a decline below this, but reduce the ventilation by degrees, and close at 75° for the day. Syringe well twice a day, and keep the inside borders supplied with water. Remove most of the smaller fruits that will not be required for the crop and which are not likely to stone satisfactorily. Thin out the shoots where too crowded, and tie down those originated from the base of the current bearing wood for next year's bearing. These ought not to be closer than 15 to 18 inches, and a similar distance should be allowed between the main branches. Stop the shoots beyond the fruit to a few joints, and remove any strong shoots, so as to cause an equalisation of the sap. Continue to disbud and thin the fruits in later houses, leaving few if any more fruits than will be required for the crop, as trees in good health under judicious management will not cast any or only a small per-centage in stoning.

Trees in late houses have set every blossom, and will need close attention to the removal of the surplus fruit; this and disbudding must be done gradually. Fumigate moderately upon the first appearance of aphides.

PLANT HOUSES.

Achimenes.—It would be difficult to name any flowering plants more suitable for the conservatory during the summer than these, and to have dwarf well-filled pans, and others in 5-inch and 6-inch pots for decorative purposes they should be raised from cuttings. Cuttings make much better plants than those raised from the tubers. The cuttings should be inserted in the pans and pots in which they are intended to flower in, for every one will strike root in a warm close atmosphere if shaded from the sun. It is not necessary to take the cuttings at a joint, for they will root as freely from the stem as the joint. After they are rooted and growing freely they should not be subjected to too much heat, or they will draw up quickly and half their beauty will be lost.

Amaryllises.—These useful bulbous plants are so accommodating that they should be grown in quantity in all gardens where choice flowering decorative plants are required. They can be had in flower successionally for months, provided they are assisted to make their growth at different periods, and are, after resting, introduced in heat and brought into flower as required. Those that have flowered should have every attention and be encouraged to make strong vigorous growth in an intermediate temperature. They should be arranged as close to the glass as possible, and must not be kept in a confined atmosphere, or their foliage will not be dwarf and sturdy. The majority that are still at rest in the greenhouse are showing signs of growth, and may be shaken out and repotted without delay in good sandy loam and a seventh of decayed manure. These need not be pushed forward in heat, but can remain in the greenhouse and be brought forward into flower as required. From this time they should be watered whenever they require it. When in active growth Amaryllises require abundance of water both at the roots and over their foliage, and when their pots are full of roots they are benefited by liberal supplies of liquid manure.

Kalosanthes.—For conservatory decoration these are not grown so much as they deserve, and when in flower they have a distinct appearance, and are very sweet-scented. Those prepared for flowering this season can now either be retarded or pushed forward. To retard them place half the batch in cold frames, and ventilate as much as possible, the remaining half should be kept in a night temperature of 45° to 50°. They should not be unduly forced in a close temperature, or their trusses of flower will be poor and the plants tall and weak instead of strong and compact. Give liquid manure freely as soon as the flower trusses are formed. Those cut back after flowering last year will not flower this season, but should, if they need it, be placed in larger pots, and stood in cold frames. Keep them close until they commence rooting, and then give abundance of air until they can be placed outside to finish and ripen their growths. To increase the stock select strong shoots from plants that will not flower, and insert them singly in 3-inch pots, placing them in an intermediate temperature until rooted. As soon as rooted pinch out the point of the young plants, which will induce them to form at least half a dozen shoots, which, if encouraged for a time in the temperature in which they are rooted, then placed in 6-inch pots when ready, grown under cool-frame treatment for a time, and finally ripened outside, will make grand flowering plants for another year. Kalosanthes do not require large pots, and succeed much better with feeding than overpotting. Employ a compost of good fibry loam, a seventh of manure, a little bone meal, and sand.

SEASONABLE NOTES ON BEES.

OUR fear that we should not escape a spell of the cold east wind has been but too surely verified. After having had a splendid revel among the Willow blossoms and various early flowers, bees have

during the last few days been compelled to exchange their delightful occupation outdoors for more prosy nursery work within the hive. Breeding had been going on at an unusual paco, and the rising temperature of the hives had been favoured by the great amount of warm sunshine and genial air without. While daily extending the brood nest the bulk of the bees had been able to get away to forage. Both pollen and honey in goodly quantity was added to the stores, and water was easily obtainable in every open leaf, for gentle showers supplied it usually in the night time, and the bees had not far to seek for it early in the day. But the cold breath of the east wind has been felt, now with leaden sky warning the bees not to quit their hives, now with treacherous sunshine tempting forth the unwary to be chilled to death in some shady spot. It is now that the bee-keeper must be on the alert to keep up the supply in the feeding bottle. Entrances should be also attended to—nearly closed when the cold air tells us that the bees will not wish to get out, and opened again should the wind blow from a warmer quarter, and the sunshine invite the workers to their pleasant task again.

The state of nearly all colonies which we have examined this spring is most forward. Where artificial means have been employed, in accordance with the teaching in this Journal, brood will now be in great abundance, and no harm will happen to the hives through a short spell of cold weather, provided that the continuous but slow supply of food is not neglected. It is in such nips of cold weather after warm that careless bee-keepers cause much damage to a stock of bees. The more carefully the stock has been hitherto fed the greater the danger by a discontinuance of such feeding now. Both queen and bees finding the supply suddenly stop become disheartened and cease, the one to lay eggs, the others to rear brood. The heat of the hive decreases not only in proportion to the decrease without, but in accordance with the cessation of activity within. No food to be collected at the feeding hole, no food to store, no movement in the hive, the bees consume less because they require less, doing less work, and thus less heat is given off from their bodies. As the heat decreases the bulk of the cluster decreases, and perhaps at last brood is left uncovered and dies chilled to death. Then follow other dangers, among them the danger that the stock will so dwindle that the survivors will not be able to clear out the dead brood, and it may in time become foul brood, and be a source of infection to a neighbourhood. This is a dark picture, but we are convinced that as much evil as we here pourtray has been effected in a district by a careless keeper of bees. It is by far better that those who cannot follow up a course of stimulative feeding without any cessation or intermission until the supply is abundant from without should let it alone altogether, see that their bees do not starve, and leave them otherwise to depend on themselves; but where the system of feeding is properly carried out, those who once try it will prove its wonderful effects in quickly working up a stock to great power, so that when the honey harvest really commences supers will be readily filled, or the extractor be fully employed.

This brings us to say a few words about supers. A correspondent was lately inquiring as to what super he should use. Our opinion is that there is but one super now which should be employed by those who wish to have their honey in a neat, portable, saleable form. The sectional super by far excels all others. They are most inexpensive; the best V-cut sections can be bought at about 4s. per hundred. Those $4\frac{1}{4}$ by $4\frac{1}{4}$ hold as nearly as possible 1 lb. of comb honey; those holding 2 lbs. measure $6\frac{1}{2}$ by $5\frac{1}{2}$. They can be had also U cut. These figures (V and U) refer to the shape of the groove cut out at each corner, in such a manner that a mere shaving of the wood is left, but this sufficient to hold the super together. They are purchased flat, and should be soaked in water for ten minutes before being put into shape. The V-cut ones are more easily put together, but the U-cut ones have this advantage, that where desired they can be more easily nailed. Only fine wire nails should be employed. A section crate is easily made. It can be a box to entirely shut in the sections, or a mere rack to support them and the dividers, covering all up, warming with drugget, flannel, &c. We have a preference for dividers of very thin wood. This can be purchased at a cheap rate from vendors. It is sawn so thin that it can be cut with scissors or pen-knife. Some use glass, some tin dividers, but wood is a warmer material than either of the former. Cardboard has been tried, but this will not do—the bees are prone to bite it into pieces. Some kind of divider should always be used between sections, otherwise one comb will be built larger than another, and the portability of the honey done away with. There is no doubt that straw supers (caps as they are called) are as readily taken possession of by bees as any we can use, but after the cap is filled it is unsaleable. The honey must be messed up before it is ready for use.

Glass supers we simply consider abominations. It is a difficult matter to get bees to begin in a bellglass, and when filled, although a pretty ornament, well—it had better remain an ornament. It is a

pity that encouragement is given to waste so much good comb honey by offering prizes at shows for bellglass supers. No, let those who want beautiful honey, portable honey, or saleable honey use sections. When warm weather returns, or even now in sheltered places with warm sunshine, bees will gather much honey from the fruit blossoms. Fruit trees are now flowering all over the country, and in the neighbourhood of orchards or fruit farms supers may be filled; but this will not be the case if too much room be given in the body of the hive. If bees and brood are covering from eight to ten frames when fruit-blossom honey is coming in abundantly a rack of sections may be put on. We would unseal a quantity of the honey in the outside frames of the hive proper, and the bees would be very likely at once to commence operations by carrying the unsealed honey aloft. Very thin guide comb should be given. The foundation made expressly for supers, if obtained of a good tradesman, will be composed of the purest beeswax, and so thin that it will be quite used up by the bees and nothing disagreeable be detected when the comb is eaten. Young bee-keepers will permit us to warn them against using thick foundation in supers. It is not pleasant when eating a piece of comb honey to find one's teeth sticking into a lump of hard wax. Such will be the case where the thick foundation made for the brood nest is used in supers. In sections we prefer to put only a narrow strip of guide sheet, and that of the thinnest manufactured.—P. H. P.

TRADE CATALOGUE RECEIVED.

Ellwanger & Barry, Mount Hope Nurseries, Rochester, New York.—*Select Roses for 1884.*

* * All correspondence should be directed either to "THE EDITOR" or to "THE PUBLISHER." Letters addressed to Dr. Hogg or members of the staff often remain unopened unavoidably. We request that no one will write privately to any of our correspondents, as doing so subjects them to unjustifiable trouble and expense.

Correspondents should not mix up on the same sheet questions relating to Gardening and those on Bee subjects, and should never send more than two or three questions at once. All articles intended for insertion should be written on one side of the paper only. We cannot reply to questions through the post, and we do not undertake to return rejected communications.

Seedling Auricula (Rev. E. F. C.).—It is a bold and effective border Alpine, but of no value from a florist's point of view. The eye is much too large, the segments rough, and the pistil far too prominent to constitute a really good flower. Such varieties as yours are not grown in pots, but are attractive on rockwork and in flower borders.

Azaleas for Naming (D. C. and R. C.).—The specimens sent are varieties, not species, of plants, and, as we have repeatedly stated, we cannot undertake to name varieties of any flowers that were originally raised from seed in gardens. The only proper mode of obtaining the names is to send flowers to the nurseryman who supplied the plants for comparing with others in his collection.

Destroying Plantains on Lawns (H. S. J.).—If you refer to page 313 last week you will find the method described of destroying them with vitriol. We know this is effective, but if the work is roughly done, and the stick rubbed on the grass, unsightly marks will be made that will remain for some time. Women or boys should not be trusted to use vitriol on lawns or anywhere else. We have extirpated plantains from large lawns in the manner referred to. We have known a kind of lawn sand that used to be advertised answer its purpose well in some cases, but not in others, but have not been able to ascertain the cause of such differing results.

Grapes Failing (C. S.).—Probably the temperature of your house is too low for Muscats. The condition of the withered bunches suggests that such is the case, and also that the wood was not thoroughly ripened in the autumn. As the Vine is so unsatisfactory we should take a cane from one of the others and inarch it on the Muscat stock, which forms a good foster parent for most varieties of Grapes. You do not say a word about the temperature of the house in which the Vine has failed.

Vines Scorched (J. L.).—Your vinery has been kept too close and moist, possibly also too cold at night. Whatever moisture is applied, either by syringing the Vines or damping the paths of the house, should be applied sufficiently early, so that the Vines and house are comparatively dry before night; and it is also equally important that the top ventilators be opened slightly half an hour after the sun reaches the house in the morning, if not sooner. Leaving houses closed too long and then throwing open the

ventilators almost to their full width results in more injury to Vines than does almost any other mistake in management. This reply was in type before your second letter reached us. Your first did not arrive in time to be answered the same week.

Apple Buds Eaten (Novice).—They have been no doubt attacked by birds, and by a little attentive observation early in the morning you might see them at work. We have not known chaffinches to attack the buds of fruit trees, but one or two bullfinches often prove very destructive. We are glad to hear you have succeeded so well in raising Auriculas.

Vine Laterals Breaking (J. F.).—The "slipping off" of the laterals is not the result of any mismanagement of the border, but is due either to their coming in contact with the roof or wires, or to imperfectly tying them. If they are tied down too soon, or the ligature is too near the point of the laterals, the latter are almost certain to "slip off." We have known Vines seriously and permanently injured by defects in tying, as blanks made by the breaking of the laterals cannot be readily occupied by fruitful wood. Do you keep the house too close and moist, and thus make the growths unusually tender?

Cutting-down Vines in Spring (Doubtful).—If Vine rods are shortened when the laterals have only just commenced growing there is such a great loss of sap that they are seriously weakened; but if they have grown a yard or so, and produced a number of developed leaves, a rod may be safely cut off if there is another on the Vine to take the sap, or if there are strong growths below the point of severance. Such Vines will lose a certain quantity of sap, but the bleeding will soon cease, and the Vine will be as healthy as ever. We have known Vines improve by this process, and we have known others ruined by beheading them in early spring.

Gardenia Buds Deformed (Mrs. Radcliffe).—We have received the deformed buds, but no letter referring to the condition of the plants, nor to the treatment or temperature to which they have been subjected. We have noticed on several occasions buds deformed when they have been produced from the small side shoots in early spring, but not to the same extent as they appear to have done upon your plants. A check when the buds are in an embryo state, arising from the soil being kept too wet, causing torpidity of the roots, is sure to result in deformity, especially if the plants are kept in a high temperature, and thus their top growth is forced too rapidly for the sluggish roots to support the flowers. That is one cause of deformed buds; another is too low temperature, in which the whole plant is paralysed, while plants in an enfeebled state by any cause do not expand their flowers freely.

Zonal Pelargoniums and their Raisers (W. E. B.).—We cannot undertake to give the names of the raisers of the thousands of varieties that have been placed in commerce during the past thirty years. You, however, only ask for six at present, and we are enabled to supply you with five of them, perhaps some of our readers can give the sixth. Tom Thumb was raised by Mr. Willson, gardener, Dallingham House, Newmarket, and was placed in commerce about forty years ago; Mrs. Pollock was raised by Mr. Peter Grieve at Culford, Bury St. Edmunds; Bijou was raised by Mr. Westwood, Turnham Green; Crystal Palace Gem by Mr. Gordon, who was outdoor Superintendent at the Palace; Lord Palmerston by Mr. Donald Beaton; and Christine was raised by Mr. F. R. Kinghorn, Sheen Nursery, Richmond, but we do not know the raiser of the variety you call Magenta Christine.

Vines not Fruiting (W. A. B.).—You do not mention the varieties, some of which naturally grow luxuriantly and bear fruit sparsely. Still, judging by the sample sent, the soil of your border is much too rich and deficient in calcareous matter. An application of lime would probably be beneficial, but the best remedy would be to lift the Vines in September, or when the fruit is cut, and place the roots in a compost of fresh loam, with an intermixture of lime rubbish and charred refuse, and half a bushel of crushed bones to each cartload of soil. The border need not exceed 2 feet in depth, nor be wider than the roots extend; and it can be kept fertile with the Vine roots near the surface by mulchings of manure. This, with thinly training the growths so that every leaf is exposed to the sun, and judicious ventilation to insure the ripening of the wood, will result in fruitful Vines. Perhaps the growths are too crowded now, and the house kept too close and moist.

Raising Anemones (J. B. Loft).—Single Anemones are readily raised from seeds, and plants raised early by sowing now commence flowering next year if grown in fertile soil. The year following they will be very fine if the tubers are not disturbed. The seed being very woolly must be separated by rubbing it with sand, and then scattered in drills about 6 inches apart and 1 inch deep, saturating them before sowing if the soil be dry. Should bright weather follow it will be advisable to shade the beds with mats or some other material, as the seed will not germinate freely; and shading is much better than watering after sowing. If the seedlings are crowded patches of them may be dug up with earth adhering to the roots, and transplanted in showery weather in summer. Fresh seed should be obtained, as the old does not germinate freely.

Salting Asparagus Beds (G. Melton).—This is certainly not an "old and useless" practice, whether you have found it valueless or not. Salt is not only an excellent manure for the crop, but it can be given safely in sufficient quantity to destroy weeds, or, what is better, prevent their growth. We never weed our Asparagus beds, because a weed is never seen on them, while we never fail to cut excellent heads of this esteemed vegetable in their season. But the soil of our beds is fertile and the plants strong. Salt will not make Asparagus grow where there is none, nor will it enable you to cut large heads from weak crowns. We apply it at the rate of about 3 ozs. to each square yard, at intervals of a week or two, and we have found by many years of experience that the dressing is beneficial. Had it been otherwise we should have discontinued the practice long ago.

Old Essays on Auriculas (N. L.).—We scarcely know what you mean by "Gilbert's Essay." Bound with "The Florist's Vade-Mecum," and mentioned on the title page, is "The Gardeners' Almanack for five years, 1683-1687. With monthly directions what ought to be done in either kitchen or flower garden for ever." And appended to it is a "Treatise of Auriculas," of which he and others were great patrons, as is told in this paragraph of its introduction:—"Peter Egerton of Boughton near Chester, Esquire: I can-

not but let every lover of flowers know his remov'd abode, to his estate at the Hall of Shaw, near Manchester in Lancashire, where he will keep up (and increase as new faces appear) his choice collection of plants and flowers. The last April I waited on him, before he removed from Boughton, and there found many Auriculas, that were not mention'd in this Compendium, and also three or four that I afterwards saw in the Pallace Garden at Worcester, belonging to Mr. Thomas Newton, gentleman to my very good lord, the Right Reverend Father in God, James Lord Bishop of Worcester. So that from Mr. Egerton's collection, who was the best florist in Cheshire, and hath the same pre-eminence in Lancashire, and Mr. Newton, who may challenge the same for skill in Worcestershire, and myself in Shropshire, and consequently from the choicest collections in these nations, I desire you accept the ensuing catalogue of the best single striped, double, and double striped Auriculas."

Various (A Lady).—You will probably not err by pinching the Vines at the top of the house, though some gardeners allow the growth to extend and hang down the back wall to encourage root-action. The precise method to adopt, as regards stopping them or permitting them to extend, cannot be determined without a knowledge of the condition of the Vines. The temperature of the house in which the Vines are flowering is right, and provided you keep the air buoyant by judicious ventilation, full bunches of fruit ought to follow. Drawing the hand gently over the bunches when they are dry early in the forenoon accelerates the setting process, so does tapping the bunches or giving the Vines a short and sharp shake, as this distributes the pollen. A soft brush lightly drawn over the bunches has the same effect. The temperature of your second house is also right. Your gardener has probably acted rightly in top-dressing the Amaryllises, also in potting the Epiphyllums, as we assume the latter needed larger pots. It is, however, very easy to overpot these plants, but as you neither indicate the size of the plants or the pots we are unable to answer your question explicitly. A light shelf in a warm house is suitable for both kinds of plants. They cannot have too much sun, and must have sufficient water to keep them growing until August, then the supply must be gradually reduced, just enough being given to keep them fresh without promoting further growth. All the sun possible and a dry atmosphere will be suitable for ripening the growth, which is essential for the formation of flowers. A bright and genial summer and a hot and dry autumn are the conditions requisite for growing both kinds of plants successfully.

Vines not Thriving (J. M.).—Your first letter was not received by us nor, presumably, was the post-card we sent in answer to your second received by you. It was not necessary to publish your letter in the Journal, and possibly if it had been inserted it would not have elicited a reply, since ordinary readers, and indeed good gardeners, would have felt that more particulars were needed to enable them to answer satisfactorily. We answer all such questions ourselves, and our reply was prepared and in type before your letter of the 17th inst. arrived. If the Vines had been heavily fruited before you had them, they ought not to have been sold for planting, as Vines that are fruited in pots are usually exhausted by the crops they produce. We can scarcely think, however, that the nurserymen you name would sell inferior—that is, exhausted—Vines. Have you asked them if the Vines were fruited before you had them? Many Vines fail because the canes are not well shortened when they are planted, or, preferably, a month or two before, if they are planted in the spring. For instance, if your Vines were 7 or 8 feet long, and were left that length, we should not expect them to do well—not half so well as if they had been shortened to a length of 3 feet. It would not do to shorten them now, they are just starting, but if cut down in the autumn to the base of the rafters, strong growth would probably follow that would bear well the following year. You might try one or two of the weakest. If they will not bear as they are you have nothing to lose, while the gain may possibly be considerable—always provided you treat them properly in respect of atmospheric moisture, temperature, and ventilation. Errors committed in these respects spoil the best of Vines; but even if the best treatment is accorded, Vines that have been heavily fruited in pots and then planted without severely shortening the canes, cannot be expected to flourish. We have never known the firm in question to sell exhausted Vines. They would no doubt dispose of such Vines if ordered, and charge a reduced price for them accordingly; but cheap Vines are dear in the end.

Azaleas after Flowering (D. E. Best).—A good place for them is a Peach house or vinery at work, or any position where slight shade can be given and a moist night temperature of 55° or 60° maintained. It is decidedly preferable to encourage them at this season than to subject them to hard forcing when wanted to flower during winter or early spring, which not unfrequently ends in failure. Plants that make their growth and set their flower buds early force into flower when wanted with ease and certainty, in fact unfold their blooms almost naturally as soon as heat is applied. When these plants have started fairly into growth and their roots are active potting can be done if required. Before commencing this operation see that the soil is sufficiently moist, so that no water will be needed for some days after repotting. Use clean pots and afford liberal drainage, which should be carefully placed in the pots and covered with a layer of moss. Good fibrous peat, with a liberal admixture of silver sand, is the most suitable compost for these plants. Remove the old drainage carefully, but do not disturb the remaining portion of the old ball. The new soil must be pressed firmly into the pots round it, so that water when applied will not pass through it and leave the old soil dry, which means serious injury and even death if the error be not quickly detected. If repotting is not necessary apply weak liquid manure, or, better still, give two or three applications on the surface during the season of some artificial manure purposely prepared for plants in pots. This in many instances will prove as beneficial as repotting.

Vines in Pots (H. S.).—Our last reply to you was on page 274. You sent stamps for numbers, but not sufficient, and accidentally omitted your address. We naturally expected hearing from you during the week, and your letter would have directed us to your question, which was placed in the envelope containing the stamps. We are now in this position of possessing your stamps while you again omit your address, and we cannot send the numbers. We can, however, answer your question by quoting Mr. Barney's description of his method of growing Vines in pots. It simply differs from

the ordinary practice inasmuch as the Vines are repotted when starting into growth. On this subject Mr. Bardney observes:—"It is by no means a common practice to remove Vines intended for fruiting from the pots in which they have been grown the previous year into those of a larger size. The system may not be new or original, but I have never seen it carried out until I practised it here in 1879 as an experiment, and was then ridiculed by more than one, who said if the Vines had been plunged in pots of a larger size, and the bottoms knocked out of those in which they were growing, there would have been some sense in the plan. This considerably daunted my courage for a time, and I entertained grave doubts about the success of transferring Vines into larger pots. However, they succeeded so well that I was tempted to try it again last year, which I did with marked success, and can now recommend the system as a safe and satisfactory one. This operation must be carried out with care both in potting and supplying the Vines with water afterwards for some time, or the result may not be very satisfactory. Grapes can be grown finer in pots both as regards bunch, berry, and flavour—in fact, in all respects when subject to repotting if carefully done—than could be the case if the Vines remained in the pots in which they were grown. After the Vines become established in their new pots they are not so uncertain as when fruited in the pots in which they were grown. They are not so liable to become dry at the roots, or to suffer from too large a supply of water, as is sometimes the case on the other system. Not unfrequently, for fear of erring on the wrong side, they receive too much water, and at a time when they are being supplied liberally with liquid manure. When repotted they have abundance of substantial food in all stages which would otherwise have to be supplied by means of the watering pot. If liquid manure is applied long after colouring commences the flavour of the Grapes is invariably deficient, and, if not supplied with stimulants, what have the Vines to feed upon in the pots in which they were grown the year previous? When repotted they do not require much feeding. A little can be given according to the richness of the compost and the size of the pots; it can be discontinued at any time, so as not to be any detriment to the flavour of the Grapes. I must here condemn the system of starting Vines in bottom heat, and having their roots in advance of the top growth, if they are intended to be repotted afterwards. I have tried it, but cannot recommend it: the fresh roots are broken in carrying out the operation, and do more harm than good, and the system is dangerous and uncertain. Before potting the soil should be in readiness, and laid for a few days before being used in the house in which the Vines are growing, to be well warmed, so that no check will be occasioned by the use of cold soil. The soil should be rich, and consist of good fibry loam, manure, and small bone dust, and a little coarse sand if needed, or any other ingredients Vine-growers prefer, but the compost given will answer the purpose well. The pots should be well drained and covered with the roughest of the compost or a few horse droppings, and then potting should be proceeded with, the crocks and any loose soil from the surface of the old ball only being removed, disturbing the roots as little as possible. The soil must be pressed firmly into the pots, gradually sloping to the Vine in the centre, and, if convenient, space should be left for further top-dressing. I have tried reducing the old ball, or, at least, disentangling some of the roots to lay into the new soil, but this is scarcely a safe plan. Before potting, the old balls should be in a thoroughly moist state, so that water will not be necessary for a few days or a week. After potting the Vines can be tied up where they are intended to fruit, and if bottom heat is to be applied after the Grapes are set they can be so arranged in tying that the pots can be drawn forward to the bottom heat without untying. If plunged the watering must not be left to a careless hand, but to one who will use the water pot judiciously, and apply the water with care and caution. Careful watering is needed in all stages, but especially until the pots are well filled with roots." We know of no means of preventing some of the eyes of layered Vines rooting more quickly than others, nor do we see what would be gained by preventing their growth.

Names of Plants (Somerset).—Acer Pseudo-Platanus. (Pen and Ink).—1, Lunaria biennis (Honesty); 2, Stachys lanata; 3, Chrysanthemum maritimum compactum; 4, Pulmonaria officinalis. (L. A. M.).—1, Sorbus aucuparia (Mountain Ash); 2, Acer Pseudo-Platanus; 3, Carpinus Betulus (the Hornbeam); 4, Kerria japonica flore-pleno. (Polly).—The truss you have sent is one of the many seedling forms of the Primrose, apparently intermediate between the Primrose and Polyanthus. We have some exactly like it, but do not consider the variety worthy of naming. We simply call it the White Primrose Polyanthus. (J. T. S.).—Sparmannia africana. (L. W.).—Amelanchier Botryapium. (J. S. Y.).—It is a variegated form of Plantago major. You would find Notcutt's "Handbook of British Plants," published at this office, useful, price 3s. 6d., post free, 3s. 8d. (C. J. S.).—Dielytra eximia.

IMPROVING AND REGULATING THE SUPPLY OF FRESH BUTTER.

(Continued from page 316.)

HAVING alluded to the breed of cows best adapted for butter-making we must next refer to the means of regulating the supply. There is no doubt that it is a good plan for dairy farmers to breed their own cattle, in order that they may be assured of the qualities of the animals when mated; in fact, we never ought to breed from a cow with a small record of milk, even if the cream is rich. On the other hand, it is not advisable to retain in the dairy any cow with a large record of milk of poor quality with but little cream. There is another way to view this matter which is not favourable to the raising of butter-making cows by the dairy farmer himself, for only a comparative few of such men, although they may attempt to rear their own stock for furnishing full records of butter, possess that knowledge of selection and discrimination of animals having all the required points and qualities which can alone secure those required in the progeny. As this is a well-known state of things we will not attempt to enforce the breeding and rearing of the farmer's own stock, but advise him to select in the markets such animals only as are not only great milk-producers, but will also furnish a record of the most cream. We must not be too positive as regards the position and situation of the dairy farmer to be able, except at great inconvenience and expense, to obtain the best butter-yielding cows, for in many of the western and north-midland counties, where the making of cheese prevails to a great extent, cows as great milkers may frequently be obtained. It is not, however, easy to obtain the Channel Island cattle without being prepared to purchase animals bought on commission, in which case the farmer is entrusting his business in the hands of men who may or may not be able and willing to furnish him with such cows as are specially suitable for butter-making. Thus it will be seen there are difficulties to contend with in each direction. The farmer must not, however, be discouraged by the prospect when entering upon his business; but we will endeavour to direct him in the right course.

First make it a rule, which may always be considered a safe one, that "like begets like," and in the endeavour to carry out this object, if we breed only from those animals on either side which possess, or in the case of male animals have descended, from stock possessing the double capacity of large records of milk and cream, the farmer will then be moving in the right track; but breeding is not really so simple a matter as many suppose. Everything depends upon judicious selection of animals for mating, not only in the first instance but ever after, so that selection, and that almost entirely, is the only security for successful operations in breeding our own stock. It often requires the utmost resolution and determination to discard some animals which have not a record of produce such as can yield full profits. This selection can only be obtained by adopting what we will call the American system of keeping a daily record of the milk given by every cow, so that by careful selection and breeding only from the heaviest milkers of the highest cream record, by sires also selected from the heavy milking dams, this will most surely produce results which may seem all but impossible. We have one more point to consider, which is the result of our own experience, for in the event of cross-bred cows being chosen for a butter-yielding dairy, that the cross should be obtained from the Shorthorn cow being mated with the Channel Island bull, the Guernsey, however, being the best; and Guernsey blood will furnish the greatest record of the richest cream.

Let us now try to ascertain the quantity of milk which should be considered as a full record from each cow per annum, for although some cows of a good breed or cross may furnish a good weight of milk per week for a period of five or even six months, still we do not consider the milking period is sufficient when limited to any such period, but should really be regulated by the time when the cow again springs for calving the next time. As a cow yielding a large quantity of rich milk requires much more care and attention than a poor milker, it becomes a more difficult question, especially if we consider improving our supply to consist of several operations in care-taking, because in neglecting either it is at variance with those systems upon which our profits are based. Feeding is an important point to which we have sufficiently referred; but health, especially during pregnancy, is of the highest importance, and as abortion amongst cows is a most serious derangement of any mode or system

of management and loss of profits, we should first consider the causes and next the prevention of its extension in the herd. First, then, is it hereditary? This we cannot say decisively; but we certainly can say it is very bad management to again attempt to breed from a cow which had aborted in the true sense of the word—that is, that the abortion did not occur through accidental or bodily injury. Under every phase of this disaster we should secure the herd against infection by removing the affected animal immediately upon discovering those symptoms which are the prelude to actual abortion to a close hospital pen, so as to completely isolate the animal from the herd. We cannot advise any attempt to breed from a cow which has aborted, even if she may be the best animal we possessed, and as there is then no excuse for her being allowed to associate with the general herd, but it should be kept in box for feeding at once for beef. It is the attempt to retain an aborted animal for further breeding purposes which is the active source of mischief hereafter. To practical farmers it is well known that the ergot of Rye is frequently formed in the seed heads of Grasses which may be left in the pastures, and is the source of abortion in its most serious form; and having this knowledge, the tufts or bunches of seed heads found in pastures may be simply rendered innocuous by running the scythe or mowing machine over the pastures in the early autumn before the seeds in the Grass heads become diseased with ergot, which it is very likely to be, especially in showery and dark sunless seasons.

The cleansing of stalls or cow-pens is an important matter after disorders or diseases of any kind has occurred on the premises amongst the cattle, therefore we recommend that the dairy houses and stalls be cleansed by washing down and rinsing the stall floors, &c., with water containing chemically pure sulphuric acid, at the rate of 3½ lbs. to forty gallons of water (for the odour of carbolic acid or chloride of lime is enough to make a cow abort, while sulphuric acid has little or no odour). As the ailments to which dairy cows are subject are many and serious, it is almost or quite impossible for the farmer or dairyman to be able even after the longest experience to understand and successfully treat various diseases to which dairy cows are liable, we therefore advise that the services of an experienced veterinary should be obtained.

(To be continued.)

WORK ON THE HOME FARM.

Horse Labour.—On farms where a close system of cropping prevails the greatest economy possible should be practised, and in order that the work for the horses on the farm may be done effectually and within a given period the horses should be powerful animals, not less than 16½ hands high, and stout in proportion. We have often ploughed with one horse on a fallow surface and scarified also, using one horse attached to a strong horse-hoe frame, and using the stout and strong tines and points in lieu of hoes, and in this way one horse will do a more valuable day's work on fallows than in any other way, and move the land, too, as deep as the plough has gone, thus breaking and pulverising the furrow completely. Some farmers will not hear of one-horse labour, but let them learn a lesson from the market gardeners near towns, who in the district in which we farmed for many years adopted the one-horse labour after our having set the example on our farm in ordinary summer tillage. The work now will be the completion of sowing Lent corn; we, however, never think of sowing Barley after the 14th of April, let the land be ever so kind or good in condition, for it seldom yields a malting sample when it is sown after that date, whereas if drege is sown at the rate of three bushels of Oats and one bushel of Barley per acre the crop would frequently prove double that of Barley sown alone. The Barley may be screened and separated from the Oats and sold for malting purposes, for Barley grown as a mixed crop will nearly always yield a good sample, whereas when sown by itself it would prove only grinding grain; the Oats being used for feeding the farm horses will also yield a large acreable produce when sown on land in good condition, either following late roots fed off by sheep, or broken up and ploughed under as manure. The seeding of Wheat after a fallow and autumn-sown makes the best preparation for seeding for a permanent pasture. We finished one field in capital condition after sowing a mixture somewhat in accordance with our seedings as stated in this Journal last month under the heading, "Seeds for Laying Land into Permanent Pasture." This field was finished on the 11th of April, the seeds were buried well, and the land left rolled without injury to the Wheat plant, although the surface was harrowed several times to bury the seed. We have also seeded several fields where the Wheat was sown after roots ploughed in, also Mustard, &c. This has worked off well without injuring the Wheat plant, the seeding being done in accordance with our statement in this Journal under the heading of "Seeds for Alternate Husbandry," given in the last week of March. We shall now be preparing for Carrot seeding, and we prefer the Red Intermediate variety, as they grow short and thick in shape, and can be dug at much less cost than any deep-rooting sort, the labour saved being an important item in their culture and lifting. These Red Carrots, too, sell better than White Belgian variety, either for the vegetable markets or the feeding of horses in towns. The shallow-rooted Carrots can be sown after Trifolium by once ploughing, but the long and deep-rooting sorts would grow forked if sown on land cultivated only by once ploughing.

Hand Labour.—The men have been busy sowing the Grass seeds, the

light seeds being sown separately from the heavy seeds, such as Clover, Sainfoin, &c., both, however, being sown by Bennett's seeding barrow. The women will be employed in the barn by preparing Carrot seeds, which is done by using leather harvest gloves for hand-rubbing the seed in order to rub off the husk or burr; the seed, when this is done properly and passed through the winnowing machine, will run as freely in the drill as the seeds like Parsley, Turnips, &c., and we find this is an important matter, and enables us to obtain much more regular and even plant than when drilled as formerly, mixed with ashes or artificial manures with which it was previously mixed. As the seedtime is now so near we will state that we prefer to drill with the garden or hand-drill on the stretch at 18 inches between the rows, which will enable the horse-hoeing to be done when the weeds begin to grow without reference to the size and forwardness of the Carrot plants, which may afterwards be safely hand-hoed without difficulty. On the home farm coppice and row woods will be finished cutting, and the cutting of the Oak timber will have been nearly done if the weather has proved favourable for stripping the bark from them. The men will be employed in the manure house if hindered in the field work in breaking down, mixing, and preparing the guano, bone superphosphate, &c., and replacing it in bags ready for use in the fields for drilling with the Carrot, Mangold, and other seeds. Cabbage plants will now soon be fit for planting out if grown in the mansion gardens, as they are frequently.

Live Stock.—The epidemic lameness in sheep, often called foot-rot, still prevails in certain districts where the roots were being fed off on cold flat-lying soils, and we notice that the ewes and their lambs also are suffering. Now, like many other stock diseases, we find that prevention is better than cure, at any rate a successful remedy when applied at the first or second day of the outbreak this lameness will yield to a remedy we have used for upwards of forty years. In the western and south-western counties where the horned Dorset and Somerset stock was kept foot-rot prevailed previous to the great outbreak of the epidemic in 1839 and 1840. But up to that time the flocks of breeding ewes and their lambs never suffered from foot-rot unless it was introduced from the before-mentioned districts, but since 1839 no district in the kingdom within our knowledge has been entirely free from the epidemic lameness when the seasons favoured an outbreak; for it is well known to all our most experienced farmers that in certain seasons the rams were lame when mated with the ewes, and thus the disease has become hereditary, and may therefore, and does occasionally, show itself, for the present season is no exception to the outbreak, especially amongst the different varieties of short-woolled down breeds. The long-woolled stock of the midland counties, &c., have not suffered so seriously as the down breeds, nor did they suffer from foot-rot in former times like the short-woolled, horned, or down breeds. Our remedy is made by the following recipe:—Take 3 ozs. of nitre, 3 ozs. of blue vitriol, 3 ozs. of gunpowder, reduced as fine a powder as possible, and mixed with hog's lard sufficient to form a glue-like paste. This has proved a much better remedy with us than any caustic lotion, but it should be applied within twenty-four hours after its appearance to prevent its spreading.

OUR LETTER BOX.

Guernsey Cows (H. S.).—Guernsey cows are much larger than the Jerseys, and give a larger quantity of milk with cream capable of being made into the very best butter and superior in colour, odour, and flavour to any other. The cows are larger frame and heavier in the carcase, and are much neater about the head and horn than they used to be. The back number of this Journal, dated November 8th, 1883, gives an excellent illustration of a well-bred Guernsey cow, called "Elegante," bred in the island. If good cattle of this breed are required they can be obtained from Mr. E. P. Fowler of Southampton, from whom we have purchased during the past forty years. The Brittany cows, which are bred largely all over that district, may be obtained of the same importer at Southampton.

Hens Dying (W. S. Hutt).—See answer in this week's *Poultry*.

REMARKS

13th.—A fair pleasant day, but without much sunshine; a little rain at night.
 14th.—On the whole cloudy and dull, with one or two sprinkles of rain, but occasional bright sunshine.
 15th.—Wet morning; cloudy afternoon.
 16th.—Dull cloudy day.
 17th.—Dull, with spots of rain at intervals; very cold N.E. wind.
 18th.—Fair, with a good deal of sunshine, but cool.
 19th.—Fair day, but not much sunshine.
 A dull cold week, with a good deal of trying N.E. wind, especially in the latter half. Temperature about five degrees below that of the preceding week, and nearly three degrees below the average.—G. J. SYMONS.

FRUIT BLOSSOM.

A LESSON OF THE SEASON.

SPRING time is with us once more rich, we trust, in promise of a summer and autumn teeming with fruit, for Pears, Cherries, and Plums are already beautiful "clouds of bloom," and Apple blossom, though not yet expanded, is equally abundant and full of promise—promise, too, that has more probability of realisation than that of the more forward fruit which now, April the 24th, has for several days and nights been in jeopardy, the thermometer falling to the freezing point, the foliage and most exposed blossom being stiffened with frost night after night, a bitterly cold wind blowing with more or less violence from the north-east, the sky being frequently overcast with heavy clouds, threatening us with showers of snow and rain, which thus far have not fallen. To this remarkable dryness of the air we owe the safety of the blossom up to the present time, but we anxiously await the result, and if the wind would change to a warmer quarter gladly should we hail genial showers then, for the fruit crop would probably be saved. Meanwhile we wait, watch, and learn something too, for with the bulk of the trees in full bloom anything approaching thorough protection is out of the question. Some blossom upon the tops of espaliers has perished from the combined effects of wind and frost, but upon every other part the healthy hue of the pistils show that the blossom has sustained no real damage, though it has apparently so repeatedly been upon the verge of destruction.

Fruit blossom, as a cultural result, is for that reason alone an important study; in it we have before us now the results of years of thoughtful care, offering to us one of those precious lessons of the seasons which we may well strive earnestly to master fully. A healthy fruit tree with a due proportion of blossom on every branch is an admirable illustration of well-balanced vigour, resultant either from judicious pruning or an entire absence of it. So regarded, the question naturally arises, Why do we prune a tree if it can be brought fully into fruit-bearing without it? The obvious answer being that we prune to accelerate the development of fruit buds, and to restrain the growth of the tree within a given space. If upon inspection now we find that our pruning has not in any or every instance led to satisfactory results, let us at once compare the condition of the faulty tree with that of any sound one in full bloom, and learn by force of contrast the cause of failure.

Excessively vigorous growth is a cause of barrenness, and must be checked in a hard-pruned tree to induce fruitfulness. Mark such trees now either for lifting or root-pruning next autumn, such a decision now enabling us to know the amount of such work, and to make arrangements for its being done early and well. To show that vigour is the cause of barrenness, and how easily it may be checked in any part of a tree, I may mention an experiment in my own practice. A pyramidal Zéphirin Grégoire Pear tree bearing very little

fruit and making excessive lateral growth, had the whole of the top branches left unpruned, the pruning of the lower branches being continued regularly, with the singular result of little wood growth in the unpruned branches, which soon became crowded with clusters of fruit buds, while the lower branches became even more vigorous, and remained barren of fruit. As an application of this lesson, the tops of several lofty pyramids both of Pears and Apples in full bearing were left unpruned, with the satisfactory result of a short growth well set with fruit buds, the lower pruned parts also continued perfectly fruitful. In another experiment the strong flow of sap was checked by twisting a wire round the stem of a Plum tree with the same result of little wood growth and plenty of fruit in the upper branches, and vigorous unfruitful growth in the lower ones. How repeatedly has it been said that nothing can prevent a tree from being most vigorous at the top, yet these experiments prove that it can be done with ease and certainty. An undue amount of vigour is, however, best restrained, or rather corrected, by judicious root-pruning, and we may now gather useful knowledge by an inspection of trees so treated one, two, or three seasons ago; the trees showing clearly that a complete change from barrenness to fruitfulness is not effected in a single season, but it is a work of gradation—a few fruit buds this year, more next year, and so on to a full crop.

Unpruned trees, or rather trees with growth only thinned and not restricted by pruning, are also an interesting study now. Dwarfing stocks induce early fruiting, and Pears on the Quince, Apples on the Paradise, and Cherries on the Mahaleb stocks may be planted thickly and left unpruned in a shallow soil. Cherries appear to wear out early under severe pruning or become shy of fruiting. Of losses under hard pruning I may mention Morello and Kentish, a tree or two of the first dying occasionally under it in any soil; of the last, all the trees which I have had in a thin soil failed, but others left entirely unpruned continue healthy and fruitful. A row containing a dozen different sorts of Cherries well illustrates the effects of pruning and non-pruning. The trees were planted thirteen years ago, and were kept carefully pruned and trained; in due course they came into fruiting, the yield being abundant and fine, and the trees were then as handsome, healthy, symmetrical pyramids as could be desired. But the promise of successional full crops of fruit was not fulfilled; the spurs soon gave signs of incipient decay, and the trees were gradually changing into a sickly barren condition. Close pruning was the apparent cause, and it was discontinued; with a free unchecked growth health returned to the trees.

Two of these may be specially selected as remarkable examples of the beneficial effects of this treatment. Belle Magnifique is 18 feet high and 13 feet in diameter at the base; most of the last year's growth is about a foot in length, some shorter and some longer; but it is all sturdy and robust, and the entire tree is just now such a cone of floral beauty as is not often seen, every branch and shoot being thick set with blossoms. From the bright red colour of its fruit it may be termed an improved Kentish, and like that good old sort it makes an excellent jam and is useful for all cooking purposes. Belle d'Orleans was never seen at its best under close pruning; its large foliage kept the interior of the pyramid so much shaded that the spurs there all died. Since it was left to grow unchecked it has quickly assumed the proportions of a tree, its great strong branches spreading upwards and outwards so fast that it is twice the size of Belle Magnifique, and it has entirely grown out of the pyramidal form at first imparted to it. It, too, has been wonderfully full of blossom and the fruit has set thickly, but it has been tried so severely by frost and wind that I am as yet uncertain about the crop. It is an excellent early Cherry, ripening in June, and the fruit is a delicious addition to the dessert, being very sweet, tender, rich, and juicy.

The attempt to train Belle d'Orleans Cherry as a pyramid

was clearly a mistake, and I must own it was done through ignorance of its peculiar habit of growth. I mention it particularly to show the folly of laying down hard-and-fast rules of culture indiscriminately. The tree proved unhealthy and unfruitful under restriction, and it was left unpruned; but because this hint from Nature was turned to account, there is no intention of laying claim to having originated an extension system. Let us have a little more common sense in fruit culture, striving to ascertain the requirements of each variety that may appear worthy of cultivation, for without close observation we run much risk of going wrong. Nor can one case be taken as a safe guide for another, however close the apparent resemblance may be. Because a strong-growing Cherry would not bear pruning it by no means follows that other exceptionally robust fruit trees may not be pruned advantageously. Hardly any sort of Plum is more vigorous than Rivers' Early Prolific, or any Apple more so than Warner's King, yet both bear close pruning perfectly, and yield crops of remarkable abundance under it.—EDWARD LUCKHURST, *Sussex*.

TEA ROSES IN WINTER AND SPRING.

No flowers are so much appreciated during the winter months as Violets, Lily of the Valley, Carnations, and Roses. These may be called common flowers in the sense that everybody grows or knows them. They are, moreover, old-fashioned, naturally sweet, and with a degree of sentiment attached to their very names. If we may place credence in Byron, Roses in December would have been in his day as surprising as snow in the middle of summer. In our time the difficulty is not so much in obtaining Roses in the last month of the year as in the first one, yet when properly managed and with appliances to do so a good supply of Roses even in those six dull weeks following Christmas is not impossible.

One of the most necessary appliances is a properly constructed and sufficiently heated hothouse in which to grow the plants during the winter season. I have grown them successfully in a low propagating pit, and others with a will to do so will doubtless find a way to produce a few flowers even where no specially appointed structure is set apart for their growth; but it may be at once stated that makeshifts in this particular instance are not to be depended on. The flowers are valuable, so that those desirous of a winter supply of Roses will find it the best and cheapest way in the end to erect a structure for their culture in the same way as they do when they desire a supply of home-grown Grapes, Orchids, or other garden produce. The structure in which our Roses are grown is a very simple one yet perfectly efficient. It is a low span pit over 40 feet long, about 13 feet wide, with a central path, with walls on each side, which support a bed of soil, ashes, and gravel, on which latter the pots are placed. The pit is heated by three rows of 4-inch hot-water pipes down each side, and ventilation is by wooden shutters at each side. During the darkest weeks a stage is erected on which the plants are placed, and thus brought quite close to the glass, a matter of great importance in January.

I find, however, that the plants require to be grown under glass during the summer months as well, and as our forcing pit can be put to more important purposes during summer and autumn a summer house for the Roses is also necessary. We are here, again, content with a very ordinary affair indeed. Some old water-tight sashes are fixed at the back to a previously existing wall, and in front rest on a plate supported by ordinary wooden paling stakes. A few rough boards with a ventilating shutter form the front, and boards and a door the ends, and we have an excellent quarter for our Roses to pass the period of their preparation and rest for winter.

The Roses remain to be considered. We cannot take a catalogue in hand, mark off the varieties, and then after planting wait results. Strict selection must be the rule. The plants must not only be free-blooming, but they must continue in flower until cool-house plants or those on walls commence a supply. Strong-growing varieties like Gloire de Dijon, Reine Marie Henriette, and Madame Berard must at once be decided against, and sorts like Souvenir d'un Ami, Jean Ducher, Madame Willermoz, Madame Falcot, Catherine Mermet, and Niphetos selected. For my own part I grow very few varieties. Niphetos is decidedly the best winter and early spring Rose. Madame Willermoz is more floriferous, but otherwise not so fine. Madame Falcot, Isabella Sprunt, and Safrano are too small. Souvenir d'un Ami I have a personal fondness for; it is to me a very forceable variety of a loveable flower. Bouton d'Or is very good for mid-winter, the buds being plump and clear yellow in colour.

Beginners ought to secure plants without delay in order to have

them as strong as possible before the next forcing season. Those on their own roots are best, but difficult to purchase, at least I have found that to be the case. Small established plants in 4 or 5-inch pots should be selected. These will most likely, in fact are certain to be, root-bound, and the first thing to be done is to shift them into 6-inch pots; then place them in a cool house, which becomes fairly warm in the daytime, and encourage all strong shoots which may start near the base of the plant to make all the growth possible, and as it progresses cut out all the weakly growths. I should hesitate about cutting any growths off until the young shoots have made a good amount of foliage. I have found severe pruning cripple the young plants considerably. The after summer treatment will consist in transferring them into larger pots as required, those 8 or 9 inches in diameter being perhaps large enough for the first year, it being much better to have a smallish pot well filled with small feeding roots than it is to employ those which are too large for the plants to entirely take possession of.

It is hardly necessary to recommend any particular soil, as cultivators are as a rule so much influenced by local circumstances in this respect. A sound open loam, to which one-third of cow manure is added, with a little superphosphate of lime or bonemeal, is the compost I employ. The plants do not root so quickly, nor do they produce such a rapid growth in this as they would in a compost of a lighter nature; but, and this is a point worthy consideration, they produce blooms for a length of time and in numbers which those plants grown in a less holding material do not.

I have now only to note a few points in the treatment of the plants while being forced. They may be either kept rather dry and cool during autumn, and thus rested for a short period, or they may be kept comparatively active all the year round. I have tried them both ways, and am inclined to recommend as little of the drying process as possible.

To proceed now with the winter treatment. We introduce our plants to the forcing pit early in November, and as the stock is freely ventilated until that time the change of atmosphere from a cool and dry one to one that is closer, moister, and warmer at once starts the plants into action. Up till Christmas 55° to 60° is a suitable temperature, from Christmas to the middle of February an extra 5° of heat is advantageous. In our pit, which is not closely glazed, no ventilation is given until the sun in March makes it necessary. As we have no top ventilators to cause cold currents of air, so mildew is almost entirely absent. I have seen it through the winter, but it had to be looked for. Later plants growing in cool houses it is almost impossible to keep free from mildew, but with forced Roses we have no trouble.

The general winter treatment consists in cutting every bud directly it is open enough to be removed, and if the shoot the bud has been growing on is weakly that is also removed at the same time. The plants require examining two or three times during the winter, and all the growths which have flowered and which are not required to produce young shoots are removed. This is a very important matter where a long-continued supply is desired, for if this system of pruning is not carried out young growths healthy and strong will not be produced from the basal buds of the former growths. When the plants are in full free growth manure in some shape is very necessary. Roses of all flowers will not live and thrive when starved. About the middle of April the plants should have a final thinning, and any strong growths duly staked and allowed room for development. Free ventilation and much less fire heat are the conditions to be observed after this. Repotting may also be seen to now, so that the plants are established before being placed in their summer quarters in May.

I may conclude by recommending such strong varieties as Gloire de Dijon, Cheshunt Hybrid, the beautiful crimson Reine Marie Henriette, and Maréchal Niel as giving the best returns when planted out and trained to pillars, or, better still, to wires on the roofs of cool houses. The flowering growths of the one season should be cut completely away, and young growths which are freely produced trained to take their place the succeeding season.—R. P. BROTHERSTON.

ONIONS—THINNED AND NOT THINNED.

SOME growers make it part of their annual work to begin thinning their Onions as soon as they are a few inches high, and do so occasionally until the plants are from 6 inches to 1 foot apart. If the soil and position are good this is a sure way to obtain fine bulbs, large, and well shaped; but further than this thin-growing has no advantage. An excessive weight of crop is not secured in this way, and large bulbs never keep so long sound as small and medium-sized ones. Of this I have had many proofs, and anyone may satisfy themselves on the point. For exhibition the bulbs must have plenty of space to develop, and when this is stated the whole of the advantage of much thinning and thin-growing has been named.

Unthinned crops are by far the most profitable. The seeds of these are sown thinly to begin with. There is no labour spent in thinning.

There are no hundreds or thousands of young plants pulled up and thrown away, but all are allowed to grow and form bulbs. Some of these, where the plants are thin, may be a few inches apart, and form bulbs 10 ozs., 12 ozs., or 14 ozs. in weight each; others may be closer, and the bulbs may be so crowded together that the majority of them may not become larger than a hen's egg; but what size more useful than this could anyone desire to keep until winter and on throughout the spring? When unthinned the weight of crop and quantity of bulbs secured from even the smallest piece of ground is astonishing, and as I have practised the system for some years against others, I can thoroughly recommend non-thinning as the best way of securing a large quantity of the most useful bulbs.—J. MUIR.

NOTES ON ORCHIDS.

CATTLEYA SKINNERI.—This most useful and free-flowering Orchid is in fine condition at Elmer's Lodge, Beckenham, the residence of John Goddard, Esq. In a small house something like 430 blooms and buds are to be seen. The plants are mostly in 32-size pots, and have on an average three flowering growths, some spikes carrying from six to eight of its beautiful rose-purple flowers, many being very rich in colour. They are growing in more heat than is generally recommended for this plant, together with fine healthy masses of *Lælia anceps*, on which forty blooms were open some time since. They receive no particular treatment, being potted in fibrous peat and supplied liberally with water during the growing season. In a cool house I noticed some good plants of *Odontoglossum stelligerum* with sixteen branching spikes, also good forms of *Cattleya Mendelli*. Of *Oncidium tigrinum* I measured pseudo-bulbs 8 inches in circumference, which produce splendid spikes in their season. All alike seem to be thriving under the care of Mr. W. Reed, the energetic and hard-working gardener.

PRUNING DENDROBIUMS.—I cannot see any advantage in this system. A plant of *D. nobile* in our own collection was neglected and not properly ripened, consequently it made a lot of young growths where the flowers should have been, with aerial roots. These were taken off and potted in the spring. They made small growth the first year, but much finer the second season. The old pseudo-bulbs were not more than from 6 to 8 inches high, but produced growths the next year 2 feet 6 inches long, proving to our satisfaction that they must draw support from the old ones, as was apparent in both instances, or why were the growths so weak and short before and so much stronger afterwards? My opinion is that while these young ones were drawing on the support of the old pseudo-bulbs, those in their proper place at the base were being robbed of the nourishment, and consequently small. *D. Dearii*, I believe, will produce good flowers for years on the same growths, and should never be cut out till dead. We have *D. thysiflorum* blooming on growths which have flowered two years previously, although they are comparatively withered. Had these been cut out it would have been a loss of from thirty to fifty flowers each. *D. densiflorum* and *D. Farmeri* frequently bloom on the old pseudo-bulbs. We have also had imported *Dendrobies* make a good growth before commencing to root. Does not this prove that the young growth is partly dependant on the old?—G. W. C.

DENDROCHILUMS.—I find that these plants are much less happy in the East India house—where from their native habitat one might expect them to thrive best—than they are when grown along with some *Odontoglossums* and *Cattleyas*. We possessed several fine plants of *D. glumaceum*, the graceful plume-like hay-scented species, and thinking that by giving them stove treatment they would increase more rapidly, we placed them along with the East Indian Orchids. The result was exactly opposite to what we desired, and it was only by drying them for a time and then cutting away all the worst portions and placing what was left in the *Cattleya* house that we saved them from certain death. The newer species, such as *D. Cobbianum* and *D. filiforme*, are equally well suited in the *Cattleya* house. Although not possessed of any showiness, these Orchids, from the delicacy and grace of their flower spikes and their fragrance, deserve a place in every large Orchid collection.

CYPRIPEDIUM NIVEUM.—Few growers are successful with this gem among Lady's Slippers, and judging from what I have seen, and my own experience in its cultivation, the cause of failure is not far to seek. Most of the *Cypripediums* prefer a shady corner in the warm house and a light peaty soil about their roots. *C. niveum*, however, is exceptional in these two particulars, as it thrives well only when planted in pure strong loam, and when placed on a shelf quite close to the glass, where all the light possible, minus direct sunshine, can reach it. Under

this treatment our plants are very satisfactory, and a large batch at the Clapton Nurseries, which is treated in a way similar to that advised is, in the strength and health of the foliage, a still further proof of the fitness of the treatment.

SOPHRONITIS GRANDIFLORA.—Although this precious little Orchid may be well grown in pans, it never looks so well as when fastened on to a short portion of Thorn or Apple branch with the bark left on and imbedded in a good layer of healthy sphagnum. Grown thus it may have a good bath daily without any risk of sourness through overwatering, and when thickly studded with its brilliant flowers it looks much more natural, more at home, than such a plant can look when planted in a pot or pan. Hung up near the glass on the shaded side of the *Cattleya* house, its little pseudo-bulbs and thick fleshy leaves are ever developing, while the roots go on creeping round the block as freely as one need wish to see who hopes for a good crop of bloom. Never grow this plant in a high temperature, or, rather, do not try to do so, or failure is sure to follow. There is a great difference in the size of the flowers of different plants of this Orchid. I have seen some nearly 3 inches in diameter, whilst others are barely an inch. They are, however, all beautiful, for beauty does not go hand in hand with size, as too many of our Orchid fanciers seem to think.

CALANTHES.—I would advise anyone not well up in *Calanthe* management not to be in a hurry to start their plants by bringing them into a warm moist house. Too early a start often means weakness and spot before the new growth gets well away. If the pseudo-bulbs have been kept in a dry house or shed where the temperature has not exceeded 55° or 60° they will still be dormant, and the longer they are allowed to remain so the better the new growth will be. When they are ready the pseudo-bulbs will of themselves show signs of activity, and then will be the time to prepare the rich mixture of loam, peat, and manure, and pot the plants.—W.

PRUNING DENDROBIUMS.—I am much obliged by "B.'s" reply this week, which is most interesting, because it records the fact of *Dendrobium nobile* blooming freely on the last year's pseudo-bulbs in the same manner as *D. Wardianum*—a most unusual circumstance, for its common habit is to flower on the two-year-old pseudo-bulbs, and it is so described by authorities on Orchids. I have pruned our *Dendrobiums*, of several sorts, for several years without doing the plants the least harm, but have not got the last-formed pseudo-bulbs to bloom yet, so far as I recollect. I have, however, looked critically into one plant to-day, and have found one pseudo-bulb of last year's growth, 1883, pushing out a few flowers, one or two just bursting through the winter bark. The plants flowered freely some time ago on the two-year-old pseudo-bulbs, and have been pruned and started, and these flower buds have pushed since. It would be interesting to know if the flowering of "B.'s" plants on the new bulbs is in any way due to pruning?—J. S.

TYING DOWN VINE SHOOTS.

TYING down the laterals of Vines is like everything else—easy enough when experience has taught the way; but beginners have often to learn at the expense of the Vines. Perhaps a few lines on this subject may not be out of place at this season of the year, when much of that sort of work has to be done. First of all I would say, Do not be in too great a hurry to tie down the laterals to the wires. If taken down when too soft they immediately begin to twist and distort themselves. If the vinery is built at such an angle as will allow of the laterals remaining free till ready to be permanently tied down so much the better; but if not, they should be gradually drawn down and secured with raffia till such time as they can be laid down to the wires and firmly tied. Another thing is, Never be afraid to use the raffia; it is cheap, and strong pieces should be used, so that there can be little chance of the annoyance of seeing shoots broken down by the weight of the bunch or the swelling of the lateral having burst the tie. When cutting the raffia after tying do not cut it too close; leave half an inch of the ends. This may seem a small matter, but it is worth attending to. When cut too closely the swelling of the lateral sometimes forces the tie loose, and consequently down come the shoot and bunch. Attention may be given to those laterals having bunches on them, in order that they may have extra strong and secure ties, those not having bunches being able, of course, to do with slighter ties; but raffia is so cheap that most people can afford to give all their Vine shoots a strong tie.

When bringing the lateral down to the wire, take firm hold

of it and bring it down steadily; no jerking should be indulged in, as the consequence may be that the shoot parts company with the main stem. Some varieties of Vines are more difficult to tie down than others. Black Alicante is often very troublesome to get down, being when in rude health very strong and brittle. When such is the case they should be left as long a time as possible, even till they are just coming into flower. By that time they are generally tougher and will endure being handled. Gros Colman, Lady Downe's, Muscats, Hamburgs, Muscadines, Sweetwaters, and many other varieties can all be handled freely in ordinary circumstances.

Sometimes, however, when Black Hamburgs come very strong they require a gradual process, and must be slung to the wires before they can be finally brought down. When tying above a bunch the tie may be made tighter than when below, as due care must be taken not in any way to impede the flow of nourishment of the bunch.

Vine shoots often swell considerably after being tied down, and allowance should be made for that, especially when, as remarked above, the tie is below the bunch. A twist of the raffia round the wire prevents the tie slipping along, as it will sometimes do when such is not done. All shoots should be as far as possible laid down to a wire that will bring them at right angles to the main stem.

When Vine rods are too crowded this cannot easily be done, and I have seen many places where the laterals were tied close in alongside the main stem, giving the Vines not half the chance they should have of getting this wood well ripened.

If these lines give confidence to any about to begin to tie Vine shoots for the first time the writer's object will have been attained. Those who know by experience all about it will still be candid enough to confess that there was once a time when they felt nervous about tying Vine shoots.—VITIS.

BERTOLONIAS AND SONERILAS.

THE beautiful markings of the foliage of these little Melastomads is not excelled by any of the large number of ornamental-leaved plants at present cultivated in our gardens, and is only equalled by the choicest of those pretty little Orchids, the *Anætochili*. These latter, however, from their being so exceedingly difficult of cultivation, might with some reason be excluded from the list of useful garden plants; whereas the requirements of the Bertolonias and their cousins the Sonerilas are simple enough to be within the reach of everyone who possesses a stove. When in good condition the rich veinings of the Bertolonias never fail to win admiration, and especially may this be said of *B. Van Houtteana*, of which the thin almost transparent leaves are covered with a close network of a deep rose colour that, owing to its crystallised surface, sparkles in the sun like the colours of beautiful birds. Nature would appear to have exerted herself in the painting of these leaves, for it would be difficult to find any plant in which her choicest handiwork has wrought with more pleasing effect. In addition to this gem we now possess a number of equally beautiful forms, for almost every one of which we are indebted to the skill in cross-breeding of *M. Van Houtte*, whose labours among these plants have yielded as good results as have been obtained by him in the improvement of the Gesneriads.

One of the most beautiful of the seedling Bertolonias is *B. Gibsoniana*, which, if such a thing be possible, is even superior to *B. Van Houtteana*. It is marked in precisely the same manner as *B. Van Houtteana*, but surpasses it in richness of colours and in the sturdier substance of its foliage. It is indeed a striking plant—perhaps a little overdone for some tastes. *B. Hrubyana*, another new form, is a silver-veined form of *B. Van Houtteana*; a third new one, *B. Rodeckiana*, is similar to the last-mentioned, with a tinge of purple added. Besides those with reticulated leaves there is a group with foliage thickly studded with white, pink, or bright red spots. Of these the best are *B. albo* and *roseo-punctata*, *B. superbissima*, *B. Mirandæ* and *B. Gladstonei*. It is noteworthy that the whole of these distinct and beautiful varieties are the progeny of *B. guttata*, a dark bronzy-leaved species; *B. maculata*, almost similar to it; *B. marmorata*, and *B. margaritacea*, which were the only species in cultivation some twenty years ago. None of these are so richly variegated as the seedling forms, careful cross-breeding, as in the case of *Crotons*, *Dracenas*, and *Coleus*, having brought out colours which were not shown in the original species.

Sonerilas are pretty little herbs not more than 6 inches high, but when in good health grow rapidly in a horizontal direction by means of their freely produced axillary branches or

stolons. Their rather fleshy leaves, which are oval in shape, and most of them some 3 inches long by an inch in width, are green or bronzy, and are blotched or spotted more or less thickly with a sparkling silvery variegation. Jewel Plants they have been called, and well they deserve the name, for the foliage of most of them has the appearance of being inlaid with sparkling jewels, rather than showing evidences of a peculiar disease, to which the physiologists tell us all leaf-variegation must be attributed. In some of them the spots run into each other, so that almost the whole surface of the leaves is silvered over. *M. Linden* has raised some beautiful forms of *Sonerila*, but has been unfortunate in giving names to more than possess sufficiently distinct characters. The first species introduced into our gardens was *S. margaritacea*, which was exhibited by Messrs. Veitch in 1864. Two other species named *S. speciosa* and *S. elegans*, both of which have green foliage, followed shortly after, along with several others of comparatively little beauty. From these the beautifully variegated forms have sprung, of which *B. Hendersonii*, *Van Houttei*, *Van de Sande*, *Madame V. Alesch* and *Devoisiana* are a selection of the best. In addition to the attractiveness of their foliage the Sonerilas are very pretty flowering plants, producing when properly managed a profusion of little bunches of pink blossoms during the last three months of the year.

The cultivation of Sonerilas is best managed in a close moist stove, where the plants should be suspended in pans or placed upon a shelf near the glass. They require shading from bright sunlight, but are liable to damp if shaded too heavily. A mixture of peat, leaf mould, and sand suits them best, and a liberal supply of water during the summer. It is doubtful whether these plants are perennial, their tendency to die in spite of the most watchful attention after flowering suggesting an annual character. To guard against total loss during winter it is necessary that a batch of cuttings should be struck late in the autumn, and as these would most likely perish along with the old plants if allowed to bloom, care should be taken to pinch out the little bunches of flowers as they appear. A position on a shelf in a not over-moist stove is the safest quarter for these young plants until the winter is over, when they will require repotting and treatment similar to that advised for summer growth. The prettiest plants I have seen were grown in pans hanging close to the glass in a moist unshaded stove. Each pan contained half a dozen plants, which were in 3-inch pots and placed in the pan with sphagnum moss about them. Thus treated the growth they made was sturdy and the foliage well finished; but it was the extraordinary production of bloom consequent on this treatment that proved its success, the whole pan looking like a closely packed bouquet of bright pink flowers, which hung over the sides of the pan so as to almost cover it.

For the management of Bertolonias the same kind of treatment as that recommended for Sonerilas will be found to answer, with the exception of the amount of light, the Bertolonias requiring more shade and as close an atmosphere as possible. In large airy structures it is advisable to place these plants under a bellglass, which should be tilted or, better still, should have an open top—a kind of bellglass which for purposes of this kind is preferable to that usually in use. Singularly enough, if kept in a dry atmosphere the leaves of these plants suffer from what is called damp, but what is really the result of wrong treatment, which weakens the foliage and makes it susceptible to decay under the slightest change of temperature or atmospheric moisture. Being natives of the moist tropical forests of Brazil, where they grow in the light *débris* under the shade of the trees, it will be apparent how essential to their welfare in our houses a moist atmosphere and plenty of water at the root must be. Bertolonias may be propagated by means of cuttings inserted in small pots in sandy peat and placed in a close frame until rooted. The most favourable season for this is of course the spring. By pegging on to a pot of sand any of the strongest leaves a quantity of young plants may be raised, as these plants form little bulbils on their foliage in the same way as *Begonia* or *Gloxinia* leaves do. If allowed to flower seeds are frequently matured, which if sown and treated like *Gloxinia* seed germinate freely and often yield new varieties.—W. W.

YARD MANURE AND WOOD ASHES.—I have been asked to state the comparative value of unleached wood ashes and barnyard manure for Apple, Peach, Pear, and Cherry trees, also in regard to composting the two. Barnyard manure varies to so great an extent that it is impossible to place a standard price upon it. What it may be worth depends upon the kind and condition of the animal, the nature of its food, the relative amount of litter mixed with it, and the amount of soluble materials removed by rain, &c. For this discussion I will take fresh horse dung as a standard, the horse having a mixed feed of one part Oats and three parts

meadow hay, the dung being free from all stable litter. This dung contains 75 per cent. of water, $2\frac{1}{2}$ per cent. of ash, and 6-10 of one per cent. of nitrogen. A ton of such manure contains 12 lbs. of nitrogen, worth 2 dollars 40 cents, and 50 lbs. of ash, containing in addition to the lime, magnesia, sulphates, chlorides, &c., 11.6 lbs. of potash, worth 77 cents., and 4.9 lbs. of phosphoric acid, worth 61 cents., or a total value of 3 dollars 78 cents. a ton, estimating these three materials at commercial rates. This calculation is made on the assumption that the phosphoric acid is all soluble in water, and that the nitrogen is as valuable for fruit trees as it is for field crops, both propositions somewhat doubtful. Wood ashes represent all the mineral elements of vegetable growth, and contain everything the farmer must give his crops except combined nitrogen. Wood ashes will vary in composition and value with the kind of wood and the part of the tree. I will take the ash of the body wood of the Beech tree as representing the average of wood ashes. A ton of such ashes contains 320 lbs. of potash, worth 16 dollars, and 105 lbs. of phosphoric acid (insoluble), worth 5 dollars 25 cents. Omitting all the other ash constituents, which have some value of themselves, the potash and phosphoric acid of a ton of such ashes are worth 21 dollars 25 cents, or nearly six times the value of a ton of fresh horse dung. For orchards I regard ashes as worth more than six times the value of barnyard manure, ton for ton. When barnyard manure is composted with wood ashes the coarse vegetable material and litter are rapidly broken down, and the manure is speedily fitted for use; but there is some loss of nitrogen in the form of ammonia, but there will be no loss of mineral matter if kept from leaching by water.—Dr. R. C. KEDZIE, *Michigan Agricultural College* (in the *New York Tribune*).

CACTACEOUS PLANTS.

(Continued from page 321.)

IN addition to the species of *Echinocactus* already noted the following are worth attention:—

E. MYRIOSTIGMA, S.D. (*Astrophytum myriostigma*).—Though in many respects this is totally distinct from the Hedgehog Cactus, yet botanically it has been found to be so nearly related to that genus that they could not be separated satisfactorily. It is very peculiar, and at a glance appears to be scarcely a living plant, so regular, rigid, and unplant-like is its form, that we might almost imagine it had been carved from a piece of stone. It seems to be an even greater departure from the forms of plant life with which we are most familiar than other *Cactææ*, strange as they are, for all vestiges of leaves or branches are lost, the spines and tubercles, their representatives in other species, have in this one disappeared, and the stem is bare except for some curious star-like scales or hairs. It forms a marked stage in the evolution of the genus, and appears to be the opposite extreme to the *Mamillaria*-like species with prominent tubercles, between which almost every gradation can be found. The stem is seldom more than 6 or 8 inches high, 3 to 5 in diameter, and has five or six broadly triangular ridges 1 or $1\frac{1}{2}$ inch deep, with an even surface and edge devoid of spines. Upon the surface are a number of small grey or whitish flattened scales or hairs, which are thickly placed on the young growth, but fall off as the plant advances in age, and the lower part of the stem is sometimes quite bare. The flowers are produced near the summit of the stem, generally several together, which open early in the day and close in the afternoon from four to five o'clock, expanding on each succeeding day for nearly a week. Plants will also continue bearing flowers from June to September.

The scales above mentioned, when examined under a microscope of moderate power, are seen to consist of small hair-like filaments radiating from a central very short stalk. Appendages of this character are seen in few members of the family, and occurring as these do in the absence of the clusters of spines, it might almost be thought that they were debased forms of these. Against that fancy is, however, the fact that the scales are dispersed over the whole surface of the plant, and appear to be merely superficial, being easily removed with the finger-nail.

E. PFEIFFERI, Zuccarini.—A bold handsome species, which at once attracts notice in a large collection, and is well worth a place in a small one. The stem is intermediate between cylindric and globular, usually 1 foot high, 9 inches in diameter. The ridges are $1\frac{1}{2}$ to 2 inches deep, and $1\frac{1}{2}$ inch across at the base, triangular, deep green. The clusters of spines are 1 inch apart, and contain several yellowish-white rigid, semi-transparent spines about 1 inch long. In the Oxford garden is a beautiful specimen of this 2 feet high, one of the finest in this country.

E. SCOPA, Pfeiffer.—The Broom Cactus is a popular name applied to this *Echinocactus*, and it is an appropriate title, for the ordinary form is suggestive of a close birch broom, or more correctly the circular brushes employed in sweeping chimneys. It is extremely distinct, and by no means wanting in beauty of the Cactoid type. The stem in most cultivated specimens is cylindrical, 4 to 8 inches high and 3 to 4 inches in diameter, but it attains the height of a foot or more, upon which the numerous small ridges, thirty or more, are very closely set, and these in turn bear extremely abundant thickly set purple hairs, which cover the plant so densely that the surface is scarcely visible. The flower is neat in form, 1 to 2 inches in diameter; the petals narrow, serrated at the point, pale yellow, with bright crimson stigmas. It is a native of Brazil, whence plants or seeds were sent to the Continent early in the present century.

E. SCOPA CANDIDUS CRISTATUS.—This is one of the most extraordinary of the numerous monstrous forms that have been obtained from seed in the Cactus family. It is also one of the most beautiful, and, though rather delicate, it well deserves the little extra attention needed to keep it in health. No one would think for a moment that it is related to the species named above, for it has undergone a most peculiar change. Instead of the regular symmetrical cylindrical stem it has become contorted, flattened, and irregularly twisted like the fasciated crest in the common Cockscomb. The surface is densely covered with small white tufts about the size of a large pin's head, from which arise numerous diminutive white hairs one-eighth of an inch long or less, and on the edge of the flattened lobes is a distinct furrow, which

follows the twisting stem in each direction. In the sun the plant has a silvery appearance, which is very beautiful, but to preserve this dust or dirt of any kind must be carefully excluded from it. It is rather slow-growing, but succeeds best when grafted on a short stem of some *Cereus*, such as *C. Baumannii*, *C. macrogonus*, or *C. peruvianus*, and less difficulty is then experienced in keeping it in good health.

B. SIMPSONI.—This is especially deserving of notice as one of the hardiest of the genus, for it has been tried out of doors in some districts, and has endured very low temperatures uninjured. It is said to be found farther north than any other *Echinocactus*, in Colorado at an elevation of 8500 feet, or still higher in more southern districts. The tubercles are loosely arranged, half to three-quarters of an inch long, with several white spreading spines and a central yellowish one. The flowers are purple or rose, rather small but numerous on the upper part of the stem. The plant is dwarf, rarely exceeding 6 or 8 inches high, and usually much less, and was introduced by Messrs. Backhouse several years ago.

E. VISNAGA, Hooker (the Toothpick Cactus).—Not only is this the most remarkable in its own family, but in some respects it is also one of the most peculiar in the whole vegetable world. Quite a sensation was created when in 1846 this extraordinary plant was first described by Sir William Hooker, in

Fig. 82.

the *Illustrated London News*, and the particulars were published of the enormous weight and size which this species attains in its Mexican home. To F. Staines, Esq., of San Luis Potosi, is due the honour of introducing the first specimens to this country, which, however, was only effected after much labour and repeated trials, as the plants had to be conveyed many hundreds of miles across a most difficult country, with very rough roads, or in some parts none at all, and the only vehicles that could be employed were large waggons drawn by mules or oxen. The plants grow in deep ravines of the loftiest

Fig. 83.—Flower of *E. Visnaga*.

mountains of the district amongst large stones and rocks, with very little soil; but there they reach an enormous size, and being very slow in growth it is reasonably supposed that some of the largest must be several hundred years old. The finest specimen yet sent to this country was 9 feet high, $9\frac{1}{2}$ feet in circumference, and weighed 1 ton; but it died after it had been at Kew about a year. Smaller but still wonderful examples were subsequently sent, the principal weighing about 713 lbs., was 4 feet 6 inches high, the longitudinal circumference was 10 feet 9 inches, the transverse circumference 8 feet 7 inches. This also has been lost, and there are now few large plants in cultivation, the two handsome specimens which so long formed a standing attraction in Mr. Peacock's collection having been lost a few years since.

The stem is cylindrical, with forty to fifty ridges, upon which the pale brown sharp rigid spines are closely set in clusters of four, 2 or 3 inches in length, and these, it is said, are used by the Mexican settlers as toothpicks. The flowers are borne at the summit of the plant in a dense woolly substance; they are 3 inches in diameter, with narrow petals serrated at the apex, and bright golden yellow in colour. The name *Visnaga*, or *Bisnaga*, is considered to be a corruption of *Bisacuta*, twice-pointed, or sharpened on both sides, in reference to the spines.

The woodcut, fig. 82, has been prepared from a photograph of one of Mr. Peacock's fine plants, which unfortunately have been lost now. These were about 2 feet high and as much in diameter, and continued in vigorous

health for several years, but ultimately were damaged by a "drip" from the roof of the house, and rapidly decayed, despite the care exercised to prevent it.—L. CASTLE.

CULTURE OF STRAWBERRIES.

FORCED PLANTS.—In most forcing establishments a planting of forced Strawberry plants is annually made out of doors in a good well-prepared piece of ground in rows 2 feet apart and about the same distance between the rows, and an equal number of old plants destroyed as soon as the crop has been gathered from them. The earliest forced plants of Vicomtesse Héricart de Thury, having been properly hardened when removed from the forcing house, should now be turned out of their pots and the balls of earth and roots be slightly reduced, repotted in clean and properly crocked pots. They can then be plunged to the rim in a warm border, either in coal ashes or the ordinary soil, until the approach of frost, when they should be taken up, the pots washed and stood on the shelves in an airy house, where a little heat can be turned on when necessary to ripen the fruit. During the interval the soil should not be allowed to become dry, and a sprinkling over the foliage with the syringe in the evenings during hot weather will keep it fresh and clean. From the time the plants have set their fruits until these begin colouring liberal supplies of diluted liquid manure should be given to the roots when necessary, which will enable them to swell finer fruits than would otherwise be obtained. Plants thus treated will yield—according to the number—a good supply of fruits during September, October, and November, when they are much appreciated for dessert.

In order to prolong the supply of ripe fruits, I should have remarked that it would be necessary to retard the fruiting of a portion of the plants, either by plunging them in a colder aspect or removing the first flower spikes they throw up after being plunged, as also the ripening of the fruit by keeping the plants in houses or pits of different temperatures. Having repotted the necessary number of plants for late autumn bearing, a planting of the same variety should then be made in a warm border, in rows as above recommended, for yielding a crop in August and the early part of September, as also for yielding early runners for layering into the fruiting pots next year. The plants, having had a thorough watering at the roots the preceding afternoon, when turned out of the pots should have the crocks and any bad leaves that may be attached to them removed, and the balls of earth and roots loosened a little all round with a pointed stick before being planted. In planting the soil should be trodden firmly around the plants, and the latter in each succeeding row set diagonally to those in the preceding one, which will afford them more room to develop than when planted opposite. This being done, a surface dressing of short dung a couple of inches thick should be laid on between the rows and plants, which, in addition to stimulating growth in the plants by its virtues being washed down to the roots, will also preserve the latter in a moist growing state.

THE MAIN PLANTING.—This, consisting of such sterling varieties as La Grosse Sucrée, Keens' Seedling, Sir C. Napier, Sir J. Paxton, President, British Queen, and James Veitch, should be made in the way recommended above in a good open quarter of the garden, and if the soil be of a loamy nature, which the Strawberry delights in, the better will be the results. The planting should be done when the ground is moist; and, in order to concentrate the energy of the plants to the development and consolidation of crowns for next year's produce, all runners and spikes emanating from them should be removed. As each variety is planted a long stout label bearing the name, number of rows, and date of planting, should be placed firmly in the ground at the end of the first row. When the plants have borne three crops of fruit they should be destroyed, and the ground, with the assistance of the crowbar, planted with Broccolis. Where forced Strawberry plants are not to be had runners of the respective varieties should be layered into 3-inch pots well filled with three parts good loam and one of horse droppings rubbed through a quarter-inch sieve, the points of these immediately beyond the miniature plants and all runners subsequently proceeding therefrom being removed. The plants, which during the interval must be kept well supplied with water at the roots, may be planted out in well-prepared ground before they become root-bound, choosing showery weather for the work. A planting of late-bearing varieties—such as Elton Pine and Oxonian—should also be made in a north border to supplement the supplies obtained from the earlier-bearing ones.

FRUITING PERIOD.—As soon as the fruit begins colouring some clean straw should be placed between them and the ground to prevent the former being damaged by grit and damp. Failing straw long litter from the stables, which a few showers and exposure will deodorise, or short grass may be substituted.

AUTUMN TREATMENT OF ESTABLISHED PLANTS.—As soon as the crop of fruit has been gathered, and the plants for forcing next year sufficiently established to be removed from the parent plants, all runners and dead leaves should be removed, and a good surface

dressing of short dung laid on between the rows and plants. This will protect, as well as benefit, the roots which are near the surface from the effects of frost. The practice of digging between Strawberry plants—happily now almost a thing of the past—cannot be too strongly condemned. The surface of the soil, however, may, with advantage to the plants, be loosened a little prior to the mulching being placed on.

PREPARING THE PLANTS FOR FORCING.—The first step to be taken in this direction is to obtain the necessary number of 32 and 24-sized pots—only a small per-centage of the latter for late varieties—and well crock them by placing a large piece of crock over the hole in the bottom of the pots, then a couple of inches of two or three smaller sizes (the smallest pieces being placed on the top), over which sprinkle a handful of new soot, and over that a few rough pieces of loam or leaves. This being done, fill the pots to within an inch of the top with similar soil to that recommended for the 3-inch pots, ramming it in firmly together as the work proceeds. The pots should then be taken to the Strawberry quarter and placed so as to reduce the chances of the runners being displaced in the process of watering the plants and gathering the fruits to a minimum. The runners, as already stated, should be layered in the centre of the pots as soon as large enough to handle, and secured there by means of small crooks—one to each plant—sufficient of which should be made beforehand out of old besoms on wet days. The best runners should be selected, and the superfluous ones cut away as the work of layering proceeds. The plants thus layered should be watered every afternoon during bright weather; this, in addition to keeping the surface of the soil moist (which is all that is needed until the roots have pushed into it), will keep the young plants clean and fresh. As soon as they have become sufficiently established to admit of their being severed from the parent plants they should be removed to a favourable situation, where they will be well exposed to the sun, and stood, not too closely together, on sifted coal ashes or on the brick walls enclosing Vine borders. From this time until the plants have completed their growth they should have liberal supplies of diluted liquid manure or weak guano water at the roots, and all runners and any small crowns that may proceed from the original and principal ones removed as soon as they appear. The pots should be plunged to the rim in coal ashes in a dry situation on the approach of frost, whence they can be taken to the potting-shed to be top-dressed, &c., and thence to the forcing departments as required.—H. W. WARD.

VIOLETS.

In answer to your correspondent "E. P." (page 324) I would advise him to treat his plants as recommended for frame cultivation during the summer, and in the autumn to lift and plant in boxes of convenient size, so that they can be elevated near the glass, where they will obtain the full benefit of the light, which is essential to the production of flowers during winter. I doubt if he will be successful in his open air cultivation if the climate is as he states it to be, unless he can obtain some frames to protect the plants during winter. Bell-glasses are unsuitable for that purpose, owing to the extremely varying temperatures the plants under them would be subject to. Your correspondent omits to state what variety he grows, and also if his neighbours experience the same difficulty as himself. I rather suspect that he has a worthless variety.—VIOLE.

THE CULTURE OF IMANTOPHYLLUM MINIATUM AND BEGONIA MANICATA.

I THINK a collection of plants far from being complete without this beautiful greenhouse spring-flowering plant. We have a grand specimen of it in the Palm house here. It has been very attractive during the past month, and is now simply perfection. It is planted out in the border, and looks quite at home. The flower scapes are from 2 to 3 feet in height, fourteen in number, and each supporting fifteen to twenty of its beautiful vase-shaped, deep orange blossoms, which are valuable for bouquets and the decoration of the dinner table. Many amateurs are prevented from growing this plant, believing it can only be brought to perfection with a stove temperature, but I am confident it can be grown well in an intermediate house. The plant above mentioned has been growing in a temperature of 50° to 60°. We also grow a few plants for earlier flowering in pots, as they are readily forced into bloom. They are not so particular as to soil. They succeed well in two parts turfy loam, one part peat, one leaf mould, with a good sprinkling of half-inch bones and silver sand. They should be potted firmly, and require careful watering. They are easily increased after flowering by division, which I prefer to seed-raising. They are very ornamental even when out of flower; their long arching sheath-like leaves are of a bright green colour, and contrast well with other plants. *Imantophyllum miniatum* is a native of Africa, and many varieties

have been lately introduced, about which I hope to pen a few notes at some future time.

Another old and useful plant which seems to try and outstrip its neighbour we have in the same border in *Begonia manicata*. Although quite distinct in habit and growth, it will succeed well with the same treatment. It has just produced thirty-five erect branching panicles of light pink flowers. The leaves are large and fleshy, the footstalks of which bear pretty red frill-like fringes. I find the flowers very useful for epergnes or trumpet vases. *Begonia manicata* is also very valuable grown in pots for table decoration or for the conservatory. We take cuttings from the old plants in May for this purpose, and when well established in 5-inch pots they are removed to a cold frame, and with careful attention will make useful plants by September, when they are taken into warmer quarters and brought into bloom as required. They continue in bloom for several months, but the foliage is liable to damp off in spots if too much water be used. It is a native of Brazil.—FOREMAN.

THE HEALTH EXHIBITION.—We are glad to state that by permission of the Council of the Royal Horticultural Society, Mr. J. Douglas Dick has been enabled to accept the appointment of superintendent of the turnstiles during the Health Exhibition, for which such extensive preparations are now being made in the gardens at South Kensington. The importance of this charge may be understood when it is stated that it involves the responsibility of accounting for all the money taken at the entrances, which last year, on the occasion of the Fisheries Exhibition, amounted, we believe, to about £80,000. The satisfactory manner in which Mr. Dick discharged his duties on that occasion has undoubtedly led to his present appointment, and the action of the Council in the matter is a graceful mode of acknowledging the services of an old and diligent official of the Royal Horticultural Society. Mr. Dick's staff numbers about forty men, the extremely wide scope of the Exhibition and its corresponding diversity being expected to prove much more attractive than the event of last year, and provision is being made for a greater influx of visitors.

— IMPROVING THE GARDENS.—The gardens in which the Exhibition just referred to will be held are undergoing a complete transformation, the work of restoring and remodelling being conducted by Mr. Barron, the Royal Horticultural Society's garden superintendent under the direction of the Duke of Buckingham and Chandos, who is working with the same zeal that Mr. Birkbeck displayed last year as the chairman of the Fisheries Committee. His Grace has entered spiritedly into the work of garden renovation, and new lawns and walks are being made, shrubs planted, and everything possible is being done to render the grounds in the highest degree attractive when the Exhibition is opened. The arrangements made for holding the Shows of the Royal Horticultural Society are much more favourable than last year, when the space allotted was in an out-of-the-way corner in the lower portions of the grounds. This year the upper and more attractive portion, with the conservatory, is secured under stipulations mutually advantageous both to the Society and the Health Committee. An active season at South Kensington is anticipated, and the Health Exhibition (with its accessories) is expected to prove a brilliant success.

— MR. G. W. CUMMINS writes that "RHODODENDRON COUNTESS OF HADDINGTON (in company with the grand *R. Aucklandii*) is now a mass of bloom at Cromwell House, Croydon. A plant more than 8 feet through is bearing hundreds of beautiful large blush-white flowers. Himalayan Rhododendrons and Cactæ are the great features of this place, and quantities of both are showing well for bloom, although many other plants are grown well besides under the able management of the gardener, Mr. W. Wright."

— THE STOKE BISHOP AND SNEYD PARK ROSE AND FRUIT SHOW will be held this year in the grounds of W. E. George, Esq., Downside, Stoke Bishop, on Tuesday, July 1st. Twelve classes, open to all amateurs, the remaining thirty-six being confined to residents of the district.

— MESSRS. BARR & SON, Covent Garden, send us a flower of a pretty and distinct double *ANEMONE STELLATA* from seed. The petals are narrow and very numerous, the outer half is bright crimson, then a broad ring of white, and shaded with crimson at the centre. It is very neat and attractive.

— "C. W." writes that "ROSE THE EARL OF PEMBROKE as an early-forcing variety is simply magnificent, producing, as it does most freely, its deep-petalled intense crimson flowers on very small plants, which are not only very distinct in colour from any other Rose, but they also possess a delicious perfume, which makes them doubly valuable. If Mr. Bennett had not raised any other Rose this alone would be sufficient to perpetuate his fame as the most successful English hybridiser of the queen of flowers."

— MR. A. J. SANDERS, gardener to Viscountess Chewton, Bookham Lodge, Cobham, sends us blooms of his double *CINERARIA ROSY MORN*, for which a vote of thanks was accorded at the last meeting of the Royal Horticultural Society. They are very full, of good form, and of a very bright rosy-crimson colour; very showy and distinct.

— MR. J. MACDONALD, The Gardens, Angeston, Dursley, sends us blooms of the *TEA ROSE ADAM*, from a plant of which he states they have been cutting since Christmas. The blooms are of wonderful size, beautifully formed, of a soft rose tint, and the foliage is similarly vigorous, proving most generous culture. This variety is very pretty in the bud stage, but rather loose when fully expanded.

— ONE of the most attractive hardy Heaths that has come under our notice is *ERICA AUSTRALIS*. Growing with some others in the Royal Horticultural Society's Gardens at Chiswick, it surpasses them all in effectiveness at the present time. It appears to be a free grower of compact habit, but not low and dense, the plant now flowering being about 18 inches high and half that in diameter. Every spray is closely covered with dark pink blooms, rendering the plant not only the prettiest Heath in the bed, but the most attractive hardy plant in the Gardens at the present time. Persons intending to plant a collection of hardy Heaths should make a note of *Erica australis*, with the view of including the species in their collections.

— THE first number of the "LITTLE JOURNAL," a new shilling monthly publication, devotes several pages to "Enterprises at Home and Abroad," and to "Workers in all Fields." The field of horticulture is not overlooked, as we find brief and highly commendatory biographical notices of Mr. F. W. Burbidge, F.L.S., and Mr. George Maw, F.S.A. The reference to Mr. Burbidge is brief, amounting simply to an enumeration of his literary works, which are very superior to many that have been prepared during the past few years, and an estimate of his character, and we believe a very fair and accurate one, from the *Nonconformist* newspaper. The article on Mr. Maw is more elaborate; his industry in collecting plants, his scientific attainments and their successful application, his mansion and garden at Bentham Hall, and his literary work being all brought under review in six or seven pages of the work. Under "Enterprises" we find an article by John Arden, entitled "Trees in their Cradle," which consists, we are bound to say, of a rather meagre description of the nurseries of Messrs. F. & A. Dickson of Chester. The "Little Journal" (Elliot Stock & Co.) is a sober work of 128 pages, well printed, variedly interesting, and will be acceptable to those who desire something more than the "light reading" that so largely prevails at the present day. It is stated that portraits would have accompanied the biographical notices, but the "workmen failed" in having them ready.

FRUIT PROSPECTS—EFFECTS OF FROST.

THE prospect of a bountiful crop of fruit has never been better in this district; and although the north and east winds with rather severe drought have prevailed, also severe frosts (7° were registered on one morning last week) the Plum, Pear, and Cherry have and are setting well outside, and Apples have begun to open their blooms. I observe much mildew and blight on the expanding leaves and flowers, also vermin, which will be very troublesome if some heavy rain does not come soon, or the syringe be brought into service with soft soap and petroleum, or, what is still more useful and safer, Hudson's dry soap.

It is both better to syringe before and after with pure water, as it wets nearly all the foliage, so that when the more expensive application is used any injury from careless mixing is avoided, and any sediment left on the trees or foliage, if strong, is rendered harmless.

Except one shower we have had no rain for some weeks, and not much sun either. We have had thunder and lightning more or less for

three weeks, and rain within five miles in plenty.—J. E. W., *Grange-over-Sands*.

THE cold easterly winds with frost on most nights of last week (18° of frost being recorded on the morning of the 23rd of April, on the previous night 10°, and the following 12°), have left their mark on vegetation, many hardy plants that had been stimulated into activity by the previous mild weather having had their tender growths injured.

Pears coming into blossom have had their tops blackened, and Potatoes cut off level with the ground, and other vegetables have suffered proportionately. This is unfortunate, as there is a great paucity of vegetables owing to the mild winter having caused them to run to seed long before the customary time. Fortunately we have fine breadths of Broccoli not injured in the slightest, and wonderfully fine Cabbages, Ellam's being far ahead of all others.

The set fruit of Plums are all blackened, Apricots are for the most part destroyed, and the same remark applies to Peaches and Nectarines. Pears, too, seem in a poor way, and have no doubt suffered severely. Raspberries have had the points of the shoots cut and are quite brown, the most forward of the Gooseberries being blackened, and those but in the flower state I fear are injured, as the bees do not care about them. Currants seem to be better, only the upper part of the bunch being damaged, and Black Currants appear little or none the worse. Strawberries do not appear to have suffered. Apples, of course, are safe, only a few sorts being in bloom.—G. ARBEY, *Paxton Park Gardens, St. Neots*.

THE severe frosts of the past week have done most serious damage, and probably in many cases have caused a total loss of the fruit crop at Girtford and the district. The blossoms of all the earlier sorts of Strawberries, and even the small unopened buds of these, as well as those of Apples, Pears, Plums, Damsons, and Cherries, are apparently all injured past recovery. The only hope remaining is for such sorts as Court-Pendû-Plat Apple, the late Strawberries and the earliest Pears, such as Doyenné d'Été, which have well set their fruit and do not as yet show signs of falling, although the ovaries seem blackened, and it is probable these Pears may disappear later on. Gooseberries, except old unpruned bushes in sheltered spots, are falling. The Red Grape Currant has a chance of a partial crop, as the blooms are not so forward, and the young foliage of Strawberries is also much injured. Raspberries in bud, as well as the young offsets of these and the common Bramble, are also affected. The buds of Vines, Walnuts, and early Oaks show similar results. Roses, where not cut back, have the young shoots and buds withered. The blossoms and stems of the earliest Peas have not escaped. The young growth of Laurels is also blackened. Hardy Ferns, Borage, Anchusa, Myosotis, Clematis Jackmanni, Violets, Chrysanthemums, and many hardy plants are much injured. Anemone japonica has suffered very severely, and even the blossom of the common white Nettle and the young shoots of Clover are shrivelled. The lowest temperature registered in the locality was, I believe, 10° of frost on the night of the 19th and 11° on the 23rd inst. Previous to last week fruits of all kinds seemed in vigorous health, and the blossom strong and indicative of a full crop, but everything much in advance of the normal period. Altogether, I never recollect such disastrous results from April frosts in the East Midlands.—T. LAXTON, *Bedford*.

A CORRESPONDENT informs us that "Fruit-growers about Southfleet and Higham in Kent state that serious mischief has been done to Cherries and Plums by the cold of this and last week. Some of the Pears have also suffered. In reference to this subject, a Covent garden salesman writes to a daily contemporary:—"The gravest fears are entertained with regard to the safety of the fruit crop for the ensuing season. We learn from some of our most important growers in Kent and Middlesex that the recent severe frost has totally destroyed the crop of stone fruit. The Pears are certainly decimated if not totally destroyed. Even the Apples have been frozen through, and therefore cannot possibly come to maturity. Black Currants are very greatly injured; but the Gooseberry, owing to its abundant foliage, has partially escaped the general destruction."

As an example of the injury to fruit in the neighbourhood of the metropolis, it may be remarked that in Streatham the fruit generally appears to have suffered most severely. In the gardens at Leigham Court House Plums have been almost entirely destroyed, Pears have suffered greatly; Cherries, Currants, Gooseberries, and even Apples, of which the flowers were not fully open, have been similarly affected. Although the promise was very good, there will not be half a crop of any kind of fruit. The lowest temperature has been about 10° of frost.

SPECIAL SOCIETIES.

THE remarks made by Mr. Dodwell at the Auricula Show, coupled with the fact that I have received the private letter to which he alludes, makes it clear that he assumes, without one tittle of evidence, that I wrote the paragraph "Fair Play," which has so excited his wrath. He states, moreover, that I shrank from coming to the meeting, although I received an intimation from him. Permit me to say that the letter was not received by me until after I returned from London on the 22nd, and that therefore I knew nothing about what was to take place. All this compels me to do what is very distasteful to me, but which I am obliged to do in order that it may be seen that whenever I do dissent from Mr. Dodwell I am not actuated by any personal feeling.

Some time before Mr. Dodwell removed to Oxford I gathered from

him that he was in much trouble and anxiety owing to pecuniary losses and a threatened action for libel. Some days after, in thinking over our conversation, it suggested itself to me that it would be a graceful and acceptable thing to present him with a testimonial on the ground of the benefits he had conferred on floriculture; but feeling that I was not a sufficiently old friend to put myself at the head of it, I wrote to Mr. Charles Turner, who cordially approved of it and warmly took it up. Now, is it likely that, having done this, I should be influenced in any remarks I may make by anything but a desire for what I consider the interests of floriculture? As I say, it is excessively distasteful to me to mention such things; but my numerous friends will appreciate, I am sure, my motives in so doing.—D., *Deal*.

ANTENNARIA TOMENTOSA.

I FIND this one of the most effective and useful edging plants, and it is the more valuable because it is quite hardy. Its colour, too, a silvery white, is very suitable for placing next either turf or Box edging, and behind it may be placed with pleasing effect almost any of the shades of colours in ordinary or carpet bedding.

Flower beds are generally made up 2 or 3 inches above the level of the turf. When ready for planting a hoe or a spade is generally run round the bed, setting the soil up with a sharp sloping edge. This is necessary for the purpose of keeping the edge of the turf clear for the edging shears, and also for the sake of neatness. In the case of carpet beds this sloping side is covered with some such suitable plant as the above named, but in ordinary bedding the edging is more generally planted on the top of it, consequently it is bare black earth for weeks till the plants grow and hang over it. Three or four years ago a neighbour sent me a few pieces of this Antennaria that he had left after bedding-out—one of those considerate actions so often met with in all true lovers of gardening. I have continued increasing my stock of it till we have now, at the special request of my employer, edged nearly all our flower beds on grass with it. And when we consider that it is permanent, and that all the keeping in order it requires is picking off the flower stems in May, the saving of edging plants and labour in keeping would be considerable where much bedding is done. The plant is very easily and quickly propagated by pulling it to pieces and replanting, as it runs on the surface and roots along the stems, and a stock of it is soon got up. We confine this edging simply to the raised edges of the beds, and when once done it will stand for a number of years and requires no attention, whether you plant the bed with ordinary bedders, carpet plants, half-hardy annuals, or mixed border fashion, and it is particularly suitable for spring beds. I commend this to all who would have their beds look neat with the least amount of labour.—R. INGLIS.

ORCHIDS AT WESTBROOK, SHEFFIELD.

IN the *Journal of Horticulture* of April 3rd, 1884, there is a paper on the above subject, which subsequently appeared in the *Sheffield Weekly Telegraph*, which I cannot allow to pass unnoticed, as I feel it disparaging to myself.

Your correspondent, "W. K. W.," says, "The late proprietor, H. Wilson, Esq., was a great lover of Orchids, and spent large sums in their purchase and cultivation, and under the skilful management of his gardener, Mr. D. Clements, his became one of the best private collections in the provinces. In 1881, however, during the illness of Mr. Wilson, which eventually terminated fatally, a large portion of the collection was disposed of at Stevens' rooms." In endeavouring to answer that, I would ask how could Mr. Wilson be ill in 1881, when he died in November, 1880, and the Orchids were sold in June or July of the same year.

Again, he says, "For a year or two from then little was heard of Orchids at Westbrook, but at the present time a great revival appears to have set in. Mrs. H. Wilson and her son, Mr. Alfred Wilson, appear to unite in supporting their able gardener, Mr. Pidsley, who is an enthusiastic and skilful cultivator, and appears likely to soon restore the collection to much of its former excellence." To what years does "W. K. W." refer when little was heard of them? I had charge of them over three years, and when I left them I defy "W. K. W." to prove that they were not as healthy and strong as any in the provinces or metropolis. He also speaks of the strength of the spikes of Odontoglossums. If he would look back in the "Garden" of May 27th, 1882, page 366, he will find notice of an Odontoglossum in flower at that time which had three spikes from one pseudo-bulb, one spike having twenty-nine another thirty-two flowers, the third I pinched off. To further show that the Orchids were good I will quote what a gentleman once said who had visited Westbrook for seventeen years. His remark was that "he had never seen anything like them before, and he would tell Mrs. Wilson so;" and in nearly the same words one of the family not residing in Westbrook told me, also referring to the plants. I will now ask Mr. Woodcock whether "nothing was heard of the Orchids" after he left the neighbourhood? Again, he says the Odontoglossums fill two span-roofed houses, each about 40 feet by 12 feet. I must once more correct him by saying that this is not so, and that one house is considerably less than the other. I should not attempt to make these corrections were it not that several gardeners of Sheffield called to see me about the subject.

In conclusion, let me state that it was neither Mr. Wilson's nor Mrs. Wilson's wish that I should leave. I will therefore allow your readers to judge between us. As for Calanthes, I had them with spikes 6 feet 6 inches long, and 3 feet 2 inches in length of bloom open at one time on one spike. I have enclosed copies of two testimonials from Mrs.

Wilson, and wish your opinion of them. Trusting to your kindness to publish the above in your next issue.—F. F.

[The testimonials are perfectly satisfactory, and we trust you will soon obtain a suitable appointment. We doubt not that had "W. K. W." had the opportunity of seeing the examples above referred to, that he would have as readily recognised the ability of the cultivator as in the case of Mr. Clements and Mr. Pidsley. We saw the Orchids when in charge of the first-named gardener, and they were very superior. The mistake as to date was obviously a mere clerical error, and the precise size of the houses is a matter of small moment. When a person visits a garden he does not as a rule take the exact measurement of the structures. It does not follow, that because two gardeners are competent, that a third is not equally skilled; but it does follow that when a large number of Orchids are sold, the smaller collection remaining, however well the plants may be cultivated, is naturally less famed, and we shall be much surprised to learn that "W. K. W." intended to convey anything more than that in his communication.]

VINES BLEEDING.

THIS season some of my Vines, young ones planted last season, have bled very much, and as I have derived a practical lesson from it I give it to others. I started my Vines with a bed of hot manure, and no fire heat. Three weeks before doing so I thoroughly drenched the borders inside on several occasions. Severe bleeding commenced a few days after, and continued until the shoots were some length. I could and would have stopped the bleeding, but accepting the theory of several writers that the so-called sap was only water without substance, let them continue until they ceased.

The Vines are just now recovering, but there is no fruit—the embryo has perished. I gathered fourteen bunches of Grapes from the same class of canes last year. Too much water is the chief cause of bleeding, and being given before growth has sufficiently advanced. Young Vines should have none, or very little, until rapid growth has begun; then for a time they cannot have too much.

Old Vines, especially those planted inside, seldom receive half sufficient water, neither summer nor winter, and this is the chief reason why Vines do not do well on the back walls of vineries. Last year I had a Black Hamburgh on a back wall with bunches overlapping each other from the roof to the floor, well hammered and finished, the foliage leathery, which were supplied with urine and soot. Bleeding is a great injury, and water is the cause.—J. E. WAITING, *Grange-over-Sands*.

PINGUICULA CAUDATA.

THIS plant should find a place in every cool Orchid house, as it is most useful and interesting. Since we have arranged several among our Masdevallias and Odontoglossums fumigating and insecticides have been dispensed with—two remedies which should be discountenanced in this house. I lately saw some valuable plants that had been completely disfigured by injudicious washing with nicotine soap, and I do not think fumigating can be done sufficiently to kill and keep down aphides without injury to the foliage and flowers of the Orchids. I presume it is the male, which flies about; this comes in contact with the leaves and flower stems of Pinguicula, which act as traps, and by catching these the others soon become extinct. *Mimulus cardinalis* is another plant that has stood in the same house some time, and has proved serviceable in catching hundreds of this troublesome insect. At one time our plants were badly attacked, but since using the traps as advised we have scarcely any insects without resorting to other means of eradicating it.—G. W. CUMMINS.

NARCISSUS JAMES DICKSON.

ON page 299 of your issue of April 17th you gave an admirable illustration of the very beautiful variety of *Narcissus incomparabilis* which has received the name of James Dickson. After giving some particulars of its reputed origin you ask for further information upon the matter, and as a few facts have come to my knowledge I send them in the hope that others may be able to add to them.

As stated in your notice the plant was named by Mr. Burbridge from flowers supplied by Messrs. James Dickson of Chester, and the same firm was awarded a certificate for it when flowers were shown at Kensington. It now appears that at the last meeting of the Committee (April 22nd) a letter was read from Messrs. Dickson to the effect that the person from whom they had received the flowers desired the name to be altered. This, however, could not be done, and the question arises as to whether the firm named above was authorised to show the flowers and receive a certificate for the variety when this is wholly in the hands of another person, as I am reliably informed it is. It is said that for some time past flowers have been sent from a certain garden in the north to the London and Manchester markets, but that the bulbs are confined to the possession of this grower, who has at present declined to part with the stock. No doubt Messrs. Dickson can explain the matter satisfactorily.—NARCISSOPHILE.

CHLORIDE OF POTASH.

YOUR correspondent who recommends the use of chloride of potash is, as "Medicus" points out, advocating the use of what does not exist. In the reply (given on page 322) to the objections raised by "Medicus," your

correspondent strives more to be funny than correct. I am anxious to profit by the information originally given, and would gladly try the manure recommended. This is, however, quite impossible if the ingredients are not correctly named. Will your correspondent, therefore, be kind enough to state what he means by chloride of potash? Is it potassium chloride, or is it potassic chlorate?—M. D.

[Potassium chloride doubtless. Scientifically, of course, chloride of potash is an impossibility; nevertheless, the agricultural potash salt is sold by that term, also as muriate of potash, which latter name is also incorrect from a strictly scientific point of view. Yet, in a late agricultural report, it was constantly referred to under the latter name.]

PRUNING ROSES.

LATE pruning and early pruning both have their advocates, and the question could scarcely be more ably debated than at various times it has been in these columns. After all, experience alone can decide it, and that not in one or two localities nor of one or two seasons.

In the present season there have been great differences of opinion and procedure. Early in the year I was present at a Committee meeting of the National Rose Society, and took the opportunity to question several authorities.

Some said, Prune early! others said, Not so.
Some said, It might do good; others said No.

One gentleman, whose opinion I value highly, meant to defer until April. I always hold here in mid-Surrey with the last week in February, but I suspect this season my Reigate friend is nearer right. Such an April as this has been does not often occur, 21° in a Stevenson-Mawley screen, and 18° on the grass, which was my case on April 23rd, cannot take place without leaving its mark.

I always think Rose trees at the end of April look about their worst, but their worst is quite exceeded this year. The too sanguine shoots are blackened and shrivelled in every open part of the garden, and, what is a still greater loss, all my forward budded Briars are heavily damaged. I have tried second pruning with some of the strongest cut-backs, rather a desperate remedy, but with a view to see how these will compare with the others. It would, I think, be both interesting and valuable if we could learn in "our Journal" from both late and early pruners how things are turning out. I am, and always have been, a strong advocate for early pruning, holding that six years out of seven it makes scarcely any difference between the end of February and the beginning of April when H.P.'s are pruned, but this year I much incline to think late pruners will come off best. But may I ask for a little more discussion of the subject?

Some better precepts if you can impart,
Why do. I'll follow them with all my heart.

—A. C.

THE AURICULAS AT SOUTH KENSINGTON.

IT has been my wont as an old Auricula grower to take notes of the shows which have now been held for some years in London and, indeed, for which I am in a certain sense responsible; for it was an expression of mine that florists' flowers were "hopelessly at a discount in the south" which led to the formation of the southern section of the National Auricula Society, and certainly thereby a great stimulus has been given to the growth of the flower, if it has not largely increased the number of exhibitors in the south, and has afforded from year to year an opportunity of lovers of the flower meeting together to talk over their favourites. Had it not been for it there are many lovers of it who would never have seen those "northern lights" Mr. Horner, Messrs. Ben Simonite, E. Pohlman, and one whom we shall see no more, alas! the recently deceased George Rudd; there would have been no opportunity of correcting the somewhat lax southern type of flower by the more rigidly exact northern taste, nor probably would the want of encouragement of the flower have led to the many new varieties being added to our lists; for however it may seem to pertain to mercenary ideas, I think that without question the offering of prizes does lead to the encouragement of the particular flower so taken up, and that, however it may be with growers for sale, amateurs will not continue to exhibit where all is expenditure and no chance of any return given.

In reporting on these shows I have, I fear, at times trod on some people's corns; but as I have never done so for the purpose of giving pain, but simply in what I believe to be the true interest of the flower which has been my earliest, and will be, I think, my latest love, I make no apology for so doing. It must be that a writer who speaks his mind will offend some people, but this we cannot help; he would be worse than useless if he were to either say what he did not think or suppress his convictions for fear of offending others. I remember what Lord Palmerston once said, that public men ought to have rhinoceros hides; and although many hard things have been said of me, I am thankful to say they have never disturbed me, but have passed by as "the idle wind which I respect not."

And now as to the particular Show in question. I do not enter into the question as to whether it was the best or not which the Society has ever held, but merely say in passing that I do not think it was. The flowers were not so numerous, and it was unquestionably a day for the southern men. We have had during the last three weeks such a spell of that "vile north-easter" that, as one of the northern men expressed to me, their plants were literally starved. They had arrived at a certain

stage, and there they remained, and I think they have learned that the application of fire heat is a dangerous tool to play with. I think that no stronger proof of the truth of this statement can be given than the fact that Ben Simonite could not even enter in the class in which he has always been a victor—the class for twelve varieties, and could exhibit in no higher class than fours. The northern flowers had in many cases a cramped appearance owing to the same cause, and even Mr. Horner's flowers, excellent as they were, were not equal to what I have seen them, and, indeed, that was his own judgment on them. We missed, too, the beautifully grown and well-flowered plants of Mr. Penson of Ludlow; and, taking altogether, I think the palm for the best plants in the Exhibition must be given to Mr. Douglas. I have sometimes found fault with his plants in former years, that they lacked refinement, and were many of them unrecognisable from their coarseness. I went this year through his class of fifty, where this fault used to be more patent, and I will not say I was surprised (for nothing that Mr. Douglas does in the way of good gardening need surprise anyone), but I was as a lover of the flower intensely pleased with the beauty of the collection. There was hardly a flower, as far as I could see, that was out of character, and while the foliage was ample, and indeed luxuriant, it had none of that cabbagey appearance which, I think, spoils the refined appearance of the Auricula. Exception may be taken to such coarse flowers as Vulcan, which is always a rough coarse flower, but exceptions prove the rule.

The very ample report given in last week's Journal obviates the necessity of my entering into the details of the Show, save to remark that the best-filled classes were those which I had some difficulty a few years ago in getting established—those for fours and twos—to be competed for by those who did not exhibit in twelves and sixes; and although one was surprised to see some names in them that one never thought of finding there, yet I believe that nothing has more tended to increase the growth of the flower than the establishment of these classes. I would rather notice some of the flowers without any special reference to the exhibitors. Taking the green edges first, there is no question in my mind than that Prince of Greens, which I at one time thought was not equal to what it was supposed to be, has of late years improved under culture. It has lost to a great extent that sprawling spidery cast of truss it used once to show, and nothing more beautiful than the plant which obtained the premier prize, exhibited by Mr. Pohlman, can be imagined. The green was so beautifully pure and the truss so excellent in arrangement. We wonder at times how it was that Colonel Taylor held so long, and indeed does still hold, so high a place amongst green edges. True, the edge is unimpeachable; but then it is very angular, and the body colour is apt to run into the paste or, rather, show underneath it, so that it has not that clean solid look which the paste ought to have. But I suppose, as I have said, that the vividness of the green edge condones its other faults, and indeed it will be seen that in the class-showing there was no other catalogued flower that took any of the eight prizes; but to my mind, when you can get, as sometimes you can, a bloom of George Lightbody or Lancashire Hero as green edges there is no flower which can approach them. I have a small truss of George Lightbody in flower with a perfectly green edge, and most beautiful it is. Will it continue so, or revert to its normal condition of grey edge? I do not say anything of the seedlings because we are not likely to see anything of them for some time to come in a general way, but there can be no doubt of the excellence of some of those exhibited.

The class of grey edges was still more numerous than the greens, for it is the most fruitful class of all; but here again we find George Lightbody carrying off the principal honours (I exclude, as I have said, seedlings), and it is somewhat singular that that grand flower Lancashire Hero does not appear as a prizewinner. Some years it has taken a very prominent place, but this year it is out of the running. Alexander Meiklejohn is another flower which at times runs George Lightbody close, and there is a deal of promise of Mr. Horner's Irreproachable, which we might rather call Unapproachable; but at present George Lightbody still keeps its place and the name of old Mr. Headly green in Auricula growers' memory. Dr. Horner is another flower which at times runs George hard, but only rarely, and the old favourite is still, I believe, the ideal of an Auricula grower's grey edge, and it will be a fortunate day for any raiser of seedlings when he can say, "I have a grey edge which beats George Lightbody."

The most limited class of all is the white edges. I mean limited as to the number of good varieties, for a large proportion of them are greyish-white, and not white. I would class as the pure white edges Acme (Read), Glory (Taylor), and Catherina (Summerscales), the two latter very old flowers; while of those flowers where the colour is more or less a greyish-white Smiling Beauty (Heap), True Briton (Hepworth), Beauty (Trail) amongst the older flowers, and I think, from what I have seen of it, Mr. Douglas's Conservative are to be classed. In the single classes it will be seen that Acme held the most prominent place, taking four out of the seven prizes, and seems to have been exceptionally good this year. The other three prizes were taken by seedlings, Conservative, Luna, and Beeswing. Taylor's Glory is a very early bloomer, and rarely puts in an appearance at these exhibitions, while Catherina is more of a favourite in the north than in the south. It is an angular flower, but its edge is unexceptionable. Trail's Beauty is sometimes very good, but when not in character it is the very reverse of a beauty, and it is inclined somewhat to be coarse. Frank Simonite was also shown well, and when John Simonite becomes more plentiful it will be a useful flower.

We now come to selfs. Some of the best were unrepresented in the single

specimen class; there was not amongst them one Pizarro, or Metropolitan or Mrs. Sturrock, or Lord of Lorne, or Lord Clyde, nor Mrs. Douglas, all good and prize-winning sorts, Mr. Horner's Heroine, a grand flower of most refined character, taking the foremost place, and Kaye's Topsy, which seems to have come out exceptionally well this year, and Blackbird, another fine sort, coming in also. Any raiser of seedlings knows that this is the class which most frequently appears in a seedling par, and all raisers of seedlings generally commence with a good self. The plants, too, of this class are generally very vigorous, with one or two exceptions, such as Duke of Argyle and Lord Clyde, and they are by the uninitiated generally the most appreciated.

I think that there could be but one feeling, and that of satisfaction, that the Veitch Memorial medal and prize went to Mr. Horner. Of course we had all set it down in our minds that it would be so, but still there was a chance that even the champion grower might come off second, although not a likely one, and we all felt that it had gone where it ought to go, to the best grower of Auriculas we have ever had.

There is one other subject of a painful character that will mark this Exhibition—the death of Mr. George Rudd of Bradford. I had not heard of his illness, and looked out for him in vain. He has not long survived his devoted friend Mr. Woodhead, and I believe will be universally regretted. I never was at his residence, but I have frequently met him, and always felt that he and Mr. Woodhead were kindred spirits. He was a keen and experienced florist and an honest and upright man to deal with; and thus the death roll becomes larger, and even amongst the limited circle of florists gaps are being continually made, but I shall ever associate in my mind with the Auricula Exhibition of 1884 the name of George Rudd.—D., Deal.

RHODODENDRON AUCKLANDII.

THIS, one of the most beautiful of the race of Sikkim Rhododendrons, is at the present time in full beauty with us, and taking into consideration the hardiness and easy culture of these plants it is somewhat surprising that they are not more frequently met with. We have here two specimens of *R. Aucklandii* bearing numerous trusses of exquisitely chaste flowers, of four to seven in a truss, and anything more beautiful is not easily conceived. According to the opinion of numerous admirers they are in point both of beauty and fragrance equal to many of the high-priced Orchids. While the care and anxiety that the latter occasionally give the grower are difficulties not easily overcome, the former which has, I am informed, being considered and even proved quite hardy by some growers, requires at the least but ordinary care and attention. The specimens above named are about 10 feet high, and one (the largest), was purchased from Messrs. Henderson & Son, St. John's Wood, as long ago as 1858. The plants when not in bloom are always noticeable on account of their bright glossy foliage.—W. W., Croydon.

[This magnificent Rhododendron is considered to be a variety of *R. Griffithianum*, and as such was figured in the "Botanical Magazine" in 1858. In Dr. Hooker's "Sikkim Rhododendrons" it was described as a species under the name of *R. Aucklandii*, but subsequently when reviewing these plants in the Horticultural Society's Journal for 1852, Dr. Hooker stated that it was the same as Wight's *R. Griffithianum*; the latter author's figure and description having been taken from an inferior specimen, and he decided to waive the name of *Aucklandii*. Still further examination of plants that flowered in Mr. Gaines', Wandsworth Nursery, in 1858, convinced him that it was really a variety of *R. Griffithianum*. The plant is found in Bhotan and Sikkim, at from 7000 to 9000 feet above sea level, in valleys where the climate is rather drier than in many other parts of this district, and was introduced to England in 1849. Our figure represents a reduced truss grown on one of Mr. Major's plants at Cromwell House, Croydon.]

DOUBLE GERMAN WALLFLOWERS—SPRING BEDDING.

VISITING the admirably managed gardens at Minella, near this town, a few days since, my attention was attracted by four large beds of Wallflowers with splendid spikes of bloom. So showy and effective were they, that I was induced to ask Mr. Crehan, the head gardener—Are those beds ever more brilliant in summer and autumn? These dwarf double, or perhaps more correctly semi-double, German Wallflowers were in bloom for the past month, and broke the customary garden monotony the whole winter. Now I am acquainted with many gardens, and I respectfully submit, is it not the practice in too many to leave the flower beds wholly unoccupied during the winter months—in fact, until the end of May or beginning of June, when the ephemeral summer bedding comes forth? Why should this be so? There is not the least reason why a magnificent bouquet should not be possible during the months of February, March, and April; and in our mild climate (we had no winter this year) we have Snowdrops, Christmas Roses, early Narcissi (*N. minor* and *N. obvallaris*) Aconites, Erythroniums, Violets on warm banks, and if not too severe, a sprinkling of Crown Anemones, &c., as early as January. The materials increase every day; and this morning,

FIG. 84.—RHODODENDRON AUCKLANDII.

what I have never noticed before in April, a bed of semi-double Cockade Ranunculi—called by the old florists "Meladorres"—commenced to unfold their blossoms. No true lover of his or her garden (even though it is used for summer bedding) should have it vacant during the months named. There is not the least reason to stop me, as has been done more than once, by interjecting, "Bulbs are very expensive for a large garden." Why I know several gardens, with more than a score beds, brilliant now, and without a bulb at all. London firms will supply a dozen distinct varieties of the above. Another dozen beds, all different, could be filled with Anemones, and next year, to be fashionable, no garden should be without a dozen varieties of Primroses, especially *P. acaulis* for souvenirs, another dozen of the best of the Narcissi, and so on. There is no difficulty in finding materials in the way of showy hardy flowers, as the lists in your columns frequently testify.—W. J. MURPHY, *Clonmel*.

NEWCASTLE SPRING SHOW.

APRIL 23RD AND 24TH.

THE Durham, Northumberland, and Newcastle Horticultural and Botanical Society held their seventh spring Exhibition in the Corn Exchange and Town Hall, Newcastle-on-Tyne. The Show was much above the average of spring exhibitions, and was considered by judges from the metropolis to be superior to any exhibition held in London this year. The Society has held their Exhibition about three weeks later than usual. This, of course, affected the Hyacinths, which were below the usual average shown at this Exhibition, but this deficiency was amply made up by the quality of the stove and greenhouse plants, which far surpassed those of any previous season.

The Judges found it necessary to award two first prizes for the four stove and greenhouse plants to Messrs. Methven and Noble, the one showing a superior collection of Orchids, and the other of greenhouse plants. The Orchids were such fine examples of high-class culture, that it is to be hoped the Society will see their way to offering a special prize for these plants another season. This will prevent the Judges being placed in such an awkward predicament in having to decide between first-class Orchids and superior examples of greenhouse plants. Appended are the awards of the Judges in Classes A and B.

In Class B, for four stove and greenhouse plants, the Society offered £11. This brought four competitors with excellent stands. Mr. A. Methven, gardener to E. Lange, Esq., Heathfield House, Low Fell, was awarded equal first prize with Mr. Noble, gardener to Theodore Fry, Esq., Woodside, Darlington, the former for an *Oncidium sphacelatum* with ten spikes, *Dendrobium Devonianum* with thirty spikes, *Dendrobium nobile* 4 feet 6 inches through, and a good plant of *Erica affinis*. Mr. Noble had an excellent *Clerodendron Balfourianum*, *Genetyllis fuchsoides*, *Tetratheca hirsuta*, and *Erica Victoria* 4 feet through, the latter a splendid specimen. With the *Tetratheca* and *Genetyllis* they formed a trio of greenhouse plants that could not be easily excelled for abundance of bloom, good training, and high culture. Mr. T. C. Ford, gardener to Mrs. H. Pease, Pierremont, Darlington, was third. His best plants were *Clerodendron Balfourianum*, *Genetyllis tulipifera*, and *Imantophyllum miniatum superbum* with eleven spikes. Mr. Neil Black, gardener to Misses Pease, South End, Darlington, was fourth; he had a good *Vanda suavis* with ten spikes.

For four Azaleas, dissimilar, Mr. T. C. Ford was first with *Duc de Nassau*, *Model*, Mr. Wm. Bull, and *Marquis of Lorne*, examples which were profusely flowered, well trained, both foliage and flowers being seen to advantage. Mr. A. Methven was second with *Stella*, *Punctata*, *Mont Blanc*, and *Triumphans*; these were trained pyramidal shape. Mr. Neil Black was third. The *Dielytra spectabilis* in this class was well shown, Mr. W. R. Armstrong, nurseryman, Elswick Road, Newcastle-on-Tyne, being first, and Mr. Larke, gardener to the Rev. W. Wheeler, Whitby, took the premier honours in the corresponding amateurs' class. *Deutzias* were also shown well, Mr. Ford and Mr. A. Methven taking first and second honours respectively. *Cytisus* also formed a special feature, Mr. J. Wood taking first prize in each class.

Amongst these spring-flowering plants the most striking were the *Spiræa japonica*, of which seven lots were staged. Some of them averaged 3 feet through in 8-inch pots. Mr. J. Noble was first, followed by Mr. J. Watson, nurseryman, Fenham Park, Newcastle. They were much admired, and so good were they that the Judges had much difficulty in making the awards. Mr. W. R. Armstrong was third. *Cinerarias* were also well shown, Mr. J. Noble being first, Mr. T. C. Ford second, and Mr. Charles Marr, gardener to J. Hedley, Esq., West Chirton House, third. For the corresponding class Mr. Noble and Mr. Marr took honours in the order mentioned.

Primulas for the time of year were creditable, Mr. McIntyre being first, and Mr. James Storrie in the corresponding class the same, followed by Mr. T. C. Ford. Mr. McIntyre was first also for *Cyclamens* in both classes, which were much admired, and considered by connoisseurs to be superior to any seen at any former exhibition, Mr. W. R. Armstrong and Mr. J. Storrie taking second position in each class. Hardy Primulas formed quite a feature, as it is seldom these lovely flowers are seen better in the north. Mr. J. McIntyre was again first with *Primula japonica alba*, *lilacina*, and *amœna*; Mr. W. L. Thompson, gardener to M. Bell, Esq., Wolsingham Park, being second with good plants of *Primulas marginata*, *abyssinica*, *ivalis*, and *intermedia*.

The table plants were not so numerous as in former years, but they were well grown and suitable for the purpose, being well carpeted with *Selaginella* and *Panicum variegatum*. Mr. J. McIntyre was first with *Dracæna gracilis*, *Cocos Weddelliana*, *Pandanus Veitchii*, &c.

Auriculas.—These were shown in good numbers, and some of them of superior quality. For twelve *Auriculas*, not less than nine varieties, Mr. E. Adams, Swalwell, was first, having fine examples of *Acme* with eight pips, which also received the premier prize for the best single plant; *True Briton* with five pips; *True Hero*, and *J. Waterton* not fully expanded. Mr. Thomas Hay, Killingworth, was second, showing *Charles Perry* with ten pips and *Trail's Beauty* very fine. Mr. Hay was first with six dissimilar varieties, *Charles Perry* being his best flower, as well as first for four dissimilar varieties. Mr. Adams was first with one green-edged variety. The green-edged varieties were on the whole good. Mr. Adams was also first for the grey-edged, as well as with the one white-edged variety, which were good. Mr. Atkinson

Winlaton, was placed first for a self with C. J. Perry, nine pips. For twelve *Alpinas*, not less than nine varieties, Mr. H. J. Watson was first, his best plant being *Brilliant*, which was very striking in colour.

For six *Polyanthuses*, gold-laced, Mr. Stobbs, Winlaton, was placed first, *George IV.* with twelve pips being his best plant, but *Exile* and *Cheshire Favourite* were also good. For other than gold-laced Mr. Atkinson showed some excellent unnamed white flowers. For a seedling Mr. Stobbs was awarded the prize for a plant much in the way of *Buck's George IV.*; in fact the Judge saw no apparent difference, but gave the exhibitor the benefit of the doubt.

Bulbs in Bloom.—These were below the usual average, no doubt attributable to the lateness of the season. For twenty-four Hyacinths there were three competitors, Messrs. H. Dewar & Co., nurserymen, Grey Street, Newcastle, being first, Mr. J. W. Watson second, and Stephen Nairn & Sons, Pilgrim Street, third. For twelve Hyacinths Mr. J. W. Watson secured the first position, and Mr. Dewar followed closely. In other classes Mr. J. McIntyre; Mr. J. Wood, gardener to H. N. Middleton, Esq., Fenham Hall, and Mr. Alfred Brown, gardener to Thomas Barnes, Esq., Whitburn Hall, were the prizetakers. For double Tulips Mr. McIntyre was first in each class. For single Tulips Mr. Watson was awarded the first place. For *Polyanthus Narcissus* Mr. J. W. Watson was first, and Mr. M. Larke in the corresponding class. Lilies of the Valley were exceptionally good, Mr. W. J. Watson being placed first with plants with seventy to eighty spikes of bloom each; the flowers were borne well above the leaves.

Cut Flowers and Decorations.—For twelve *Camellia* blooms Mr. W. L. Thompson was first with *Alba Plena*, *Duc de Sutherland*, *Sarah Frost*, and *J. Lind*. Mr. A. Methven for a bridal bouquet. Mr. Mark Hutchinson, Toward Road, Sunderland, was first with an arrangement of *Liliums*, *Amaryllys*, *Niphetos Rose*, and *Tuberoses*, all neatly edged with *Adiantum gracillimum*. Mr. Jupp was second. For a drawing-room epergne Mr. Webster, Sunderland, was awarded the first prize. The top tiers consisted of *Spiræas*, and double *Pelargoniums*, draped with *Tropæolum*; the second *Begonia Moonshine*, *Roses*, and *Azaleas*; the base was heavy but not formal with *Azaleas*, *Narcissus poeticus*, *Roses*, this being margined with *Davallia Mooreana*. Mrs. E. Adams, Swalwell, was second, and Mr. M. D. Thompson, gardener to Lindsay Wood, Esq., third. The last was a very tasteful epergne, and much dissatisfaction was expressed that it was not placed first. It has been usual for all the Judges to judge the epergnes and cut flowers, thus acting as a sort of committee. In the above case, unfortunately, one Judge was only present, but the vase was not quite erect, and no doubt this influenced the award. In other classes Mr. Thompson, Mrs. Adams, and Mr. J. McKenzie, florist, Benwell, were prizetakers. For hand bouquets Mr. Hutchinson and Mr. Webster won the honours in each class. For twelve *Rhododendron* trusses Mr. T. C. Ford was first with *R. ciliatum Veitchianum* (good), *Duc de Rohan*, *Magnificum*, &c.; Mr. Neil Black being second with *Gibsoni*, *Countess of Haddington*, and *Purity*. These were really a very grand show. For twelve bunches of *Azaleas* Mr. J. McIntyre was first with *La Reine des Blanchés*, *Duc de Nassau*, *Comtesse de Flandres*, *Dr. Morren*, *Imbricata*, &c.; Mr. C. W. Baynes, gardener to R. Dickinson, Esq., Shotley House, being second. For Pansies, Fancy and dissimilar, Mr. Atkinson was first in each class. For twelve *Roses* on stands Mr. Brusby, Pendower, was first with handsome blooms of *Maréchal Niel*, large in size and rich in colour; Mr. C. W. Baynes being second.

Miscellaneous.—Amongst the exhibits not for competition, one of the finest collections of hardy *Narcissus* ever seen in the north was staged by Mr. W. J. Watson, including flowers of many beautiful varieties. W. Fell & Co., nurserymen, Wentworth Nurseries, Hexham, showed as usual an excellent collection of hardy *Coniferae*, including such varieties as *Cupressus Lawsoniana* and *Dicksoniana*, *Thuja Vervaeana*, *Thujopsis Standishii*, *Retinospora filifera*, and the curious *Libocedrus decurrens aurea*.

The Committee and Secretary merit congratulation on the success of the Exhibition, which was in a great measure attained by ungrudging labour. The Committee and Judges dined at the Turf Hotel, where the Treasurer, Thos. Gray, Esq., presided, with Mr. Plinner in the vice chair.

NOTES AT UPPER HOLLOWAY.

THE extensive collections of choice and beautiful plants in Mr. B. S. Williams's nursery at Upper Holloway have rarely been in better condition than at the present time, for every department possesses some attraction worthy of notice. Numerous as are the houses devoted to plants, the rapidly increasing stock requires more adequate accommodation, and to afford this several houses are in preparation, which will doubtless soon be filled when completed, and furnish additional attractions for horticulturists in search of novelties of sterling merit or older well-proved favourites. It is most pleasing to observe the activity prevailing throughout the establishment, as indicating that the general demand for good plants is very far from decreasing, and indeed there is substantial evidence that a great advance is being made in many classes of plants. To note a few of the most striking inmates of the houses we may commence with the

ORCHIDS.—These, it is known throughout the civilised world, are a standard attraction, and it is of little consequence what period of the year a visitor may select for his journey thither, there is always something rare, valuable, and beautiful to be seen in flower, and the utmost care is exercised to maintain this character. All the best varieties obtainable are added to the collection, and every novelty is secured and tested as soon as possible, the comparison with the many other varieties or species being most useful in proving whether the new comer deserves a position or not. Just now the *Cattleyas* and *Lælias* are in grand condition; about 500 or 600 sheaths are showing, which in the course of a few weeks will produce a display of unsurpassed beauty. Some are already flowering, and amongst them may be mentioned the profuse rosy purple *Cattleya Skinneri*, which is one of the really useful Orchids. Several pretty varieties of *C. Mendelli*, diversely, richly, and delicately tinted are noticeable; while of *C. Trianae* the collection is large and valuable, and scores of plants are promising a handsome display later on.

Odontoglossum vexillarium is of course represented by many fine varieties, but there is one which bears the appropriate title of *splendens*, which is probably the finest in cultivation, and merits special attention. It is the same variety as that of which a small plant was sold at Mr. Stevens' rooms a short time since for twenty-six guineas, and at the last Kensington meeting Mr. Williams was awarded a first-class certificate for the plant now noted. With such indications of its quality something good might be expected, and no one who saw it would be disappointed. The flowers are not of the largest size, but of excellent form; the petals round, even, and of great substance, while the colour is a uniform deep rose, which is relieved by a small blotch of white at the base of the lip. The variety is very floriferous, as a small but healthy plant in a 48-size pot has four spikes of six and five flowers each, and suspended from the roof of one of the houses it has a grand appearance.

Vandas are in their customary sturdy health, some plants of *V. suavis* and *V. tricolor* bearing a number of large spikes of their rich flowers. These form a beautiful bank, and near them is a plant of *Dendrobium superbiens* with a spike 2 feet long, bearing thirteen large flowers, and the condition of the plant indicates that whatever difficulties some find in its culture have been effectually overcome at Holloway. Though this is placed in the general collection, it may be remarked that a house is now devoted to the *Dendrobiums*, of which a great number are grown, *D. crassinode*, *D. Ainsworthi*, *D. Wardianum*, and similar well-known

. 85.—*Oncidium leucochilum*.

species being in strong force. A wonderful plant of *D. Calceolus* on a block, and showing forty or fifty spikes, will be very handsome in a short time, and worth a long journey to see.

Cypripediums constitute another feature, as many species are now flowering, and others will shortly take up the display. Of the distinct *C. lævigatum* a beautiful variety is flowering, deeply coloured and heavily striped. The rare *C. Druryi*, with its neat yellowish flowers, is worth a place in every collection, as it is unlike all others in cultivation. *C. caudatum* and *C. Haynaldianum*, of which the specimens are very large, are showing flowers abundantly, and numerous others are similarly good.

Odontoglossums and *Oncidiums* contribute considerably to the floral attractions, and among the former *O. Alexandræ* with its varieties alone constitute a beautiful show. The flowers of many forms of this plant are distinguished by their perfect symmetry, wax-like substance, and purity and delicacy of colour. It is not easy to decide which are the most pleasing—the white or the rose-tinted varieties. They are both beautiful, and in their finer developments extremely valuable. The darkly marked *O. Halli* furnishes a striking contrast to the *Alexandræ* type. The dwarf and charming *O. Rossi majus* and the almost constantly flowering *O. Erstedti* are notable and useful, while amongst the long-lasting *Odontoglossums* may be named *O. cariniferum*, which has several very large panicles, and has been in flower since Christmas. Though not so showy as some species this is well worth more attention, as it is a free grower, and the long duration of its flowering period renders it especially valuable wherever a display has to be maintained. The sepals and petals are brown, the tip white, and the column purple—a peculiar but not displeasing contrast of colours.

Thoroughly useful is the profuse *Oncidium concolor*, which is now brightening several of the houses with its abundant spikes of pure yellow flowers. Another free and pretty species is *O. leucochilum*, of which a side branch of one of the panicles is represented in fig. 85. Like most Orchids this species is naturally variable, and forms of widely divergent

merit have been introduced, but in clearness of the markings and richness of colour the one under notice is unsurpassed. The sepals and petals, which in some are of quite a greenish tinge indistinctly marked, are in this one boldly and regularly barred or spotted with brown on a yellow ground, the lip being of good size and pure white. The panicles are 3 or 4 feet long, but have been produced as much as 8 or 9 feet long, and they last for considerable time in flower.

In other houses *Masdevallias* are numerous and good, as well as many other Orchids which cannot be enumerated now, as other departments demand a word or two.

AMARYLLISES.—For something like a quarter of a century Mr. Williams has paid attention to the improvement of Amaryllises, and many highly meritorious varieties have been raised and honoured with certificates. Especial efforts have been made to heighten and diversify the colours, and with a large share of success, for some of the best coloured varieties have emanated from the Holloway nurseries. The stock now includes thousands of plants in all stages, from seedlings which have not yet flowered to specimens of considerable size and age. These occupy several houses, but the deficiency of accommodation has been long felt, and to better provide for them a span-roofed house has been commenced 80 feet long and 18 feet wide, which it is intended to devote to Amaryllises. There the collection will be seen to some advantage, and some brilliant displays may be expected which under the present arrangements would be impossible. The plants have been in flower for some weeks now, and several of the earlier varieties are past their best, but the finest of those still in flower are the following:—

Scarlet.—General Gordon, very rich, fine form; *Grandidens*, dark; *Cruentum*, handsome form, most effective; *Quartermaster*, dark; *William Pitt*, glowing, with white bars at the base; *Firefly*, very bright; *Unique*, an old and interesting variety; *Magniflora*, of great size; and *Dr. Masters*, one of the best formed types. *Crimson.*—*Beauty of Reigate*, dark and rich; and *Crimson King*, a handsome variety, with a white central bar. *Striped.*—*Loveliness*, white and rose; *Holfordi*, crimson and white; *Cleopatra*, crimson and white; *Guiding Star*, crimson and white; and *bicolor*, also crimson and white. Mrs. B. S. Williams is still the best of the white-flowered varieties, very pure and beautiful. A large number of careful crosses between the best varieties have been made this season, and will add, no doubt, to the number of useful varieties.

The houses of Ferns, *Nepenthes*, *Camellias*, *Ericas*, *Palms*, and miscellaneous stove plants, amongst which the *Dipladenias* are particularly numerous and healthy, are all attractive, as novelties abound in every department, and all alike are distinguished by a most satisfactory condition.

WHAT IS AN AMATEUR?

THE question as to what is an amateur, which seems now to be perplexing the minds of the members of the National Auricula and Carnation Societies, was some time ago brought before the National Rose Society's Committee, and their decision (comprising, as the Committee does, most of the leading nurserymen and amateurs) may be, I think, accepted as the best decision to be arrived at. It was felt that so many gentlemen and even noblemen disposed of the surplus stock of their gardens that it would be difficult to say that one who did so was not an amateur, although in some cases they sailed perilously near the wind; but that each case should be separately adjudicated upon by the Committee. But it was their unanimous opinion that when anyone published a catalogue and solicited orders he must be classed as a nurseryman; and, indeed, one case in which an amateur who took up Roses as his hobby but afterwards did so, did occur, but then with good taste he voluntarily withdrew from the amateur classes.—OLD EXHIBITOR.

ROYAL HORTICULTURAL SOCIETY.

SCIENTIFIC COMMITTEE, APRIL 22ND.

THE following abridged report we were unable to insert last week. There were present at the meeting A. Grote, Esq., in the chair, Messrs. Pascoe, Mangles, MacLachlan, Glaisher, Wilson, Smith, Boulger, Ridley, Loder, Houston, and Rev. G. Henslow.

Rhododendron Hybrids.—Mr. Mangles exhibited a large basketful of beautiful *Rhododendrons*, including the following remarkable hybrids:—Anderson Henry, a triple hybrid, raised by Mr. A. Henry from *R. formosum* crossed by *R. Dalhousiae*, crossed by Mr. Nuttall, and with very large white funnel-shaped flowers with yellow throat—the foliage is dark green; *R. Veitchii* crossed by *R. Edgworthii*, with large crimped petals and wide mouth—highly scented; it is called Otto Forster; a hybrid between *R. Thomsoni* and *R. Fortunei*, of crimson flower and dark foliage. Its stamens have "contabescent" or imperfect anthers, not unfrequently seen in hybrids. Another called the Countess of Haddington is the offspring of *R. Dalhousiae* crossed by *R. ciliatum* and Princess Alice, raised from *R. Edgworthii* crossed by *R. ciliatum*. He also showed the following species:—*R. virgatum*, a species with small pink axillary flowers interspersed amongst the leaves, not unlike a *Weigela*; *R. pendulum*, a rare species, described as an epiphyte upon Oaks, and remarkable for the closely tomentose under surface of the leaves. It refuses to hybridise.

The Weather of the Winter 1883-4.—Mr. Glaisher read an interesting paper on the remarkably high temperature of the last winter. See next page.

Arum proboscideum.—Mr. Wilson exhibited a blossom of this curious flower, a native of Italy.

Equisetum telmateia.—Mr. Houston exhibited specimens showing spikes with branched apices, covered with sporangia in every case.

Narcissus Bulbocodium (Monstrous).—Mr. Boulger showed a species of *Narcissus Bulbocodium* with several flowers confluent and the parts variously multiplied in consequence.

Calceolarias.—Mr. Henslow reported on the monstrous *Calceolarias* brought by Mr. Smee at last meeting. They both consisted of two flowers combined, but while in one case the two "slippers" were distinct, in the other the two adjacent sides of the two slippers were coiled up into a spiral, and thrust into the common interior of the two petals.

Ferns Grown in the Dark.—Mr. Henslow showed several petioles of fronds (the lamina not being developed) grown in total darkness in a temperature varying from 60° to 90°. They were of a pale green colour, while Peas germinated with them were void of chlorophyll.

Whip Made of Seaweed.—He also showed a whip made by twisted fronds of a Fucaceous Seaweed, probably a *Laminaria*, and a pipe made in the Hartz Mountains—the stem of a branch of *Pinus*, a head carved formed the bowl, with a head composed of *Usnea barbata*, and tassels of fruit of Alder.

Ornithogalum, sp.—Hon. and Rev. J. T. Boscawen sent a spray of handsome species, with large white scented flowers. It was referred to Mr. Baker for determination.

THE MILDNESS OF THE SEASON.

FOR the following remarkable particulars as to the temperature of the past quarter at Greenwich, as prepared by Mr. Glaisher, we are indebted to the Editor of the *Gardeners' Chronicle*.

The mean temperature of January was 43.9°, being 7.4° and 5.3° above the averages of 113 years and 43 years respectively. Back to 1771 there have been but only two instances of a mean temperature for January being as warm as 43.9°, and in 1796 45.3°, and 1834 44.4°.

The mean temperature of February was 41.9°, being 3.2° and 2.4° above the averages of 113 years and 43 years respectively. Back to 1771 there have been twenty-four previous instances of a mean temperature being as high as 41.9°—viz.,

1775 .. 41.9°	1849 .. 43.9°	1867 .. 44.7°
1779 .. 45.3°	1849 .. 43.4°	1868 .. 43.0°
1794 .. 44.7°	1849 .. 43.2°	1869 .. 45.9°
1809 .. 44.1°	1850 .. 44.7°	1871 .. 42.4°
1817 .. 42.6°	1856 .. 42.0°	1872 .. 44.8°
1822 .. 43.3°	1859 .. 43.1°	1877 .. 43.5°
1826 .. 42.2°	1861 .. 42.1°	1873 .. 42.2°
1833 .. 42.4°	1863 .. 42.1°	1883 .. 42.6°

The mean temperature of March was 44.5°, being 3.4° and 2.8° above the averages of 113 years and 43 years respectively. Back to 1771 there have been eleven previous instances—viz., in

1777 .. 44.6°	1822 .. 47.3°	1871 .. 44.9°
1779 .. 47.0°	1830 .. 45.8°	1872 .. 44.6°
1780 .. 42.2°	1841 .. 46.2°	1882 .. 46.0°
1815 .. 45.0°	1842 .. 44.9°	

The mean temperature for the quarter ending March was 43.4°, being 4.7° above the average of 113 years, there being only three instances of a mean temperature of a quarter as high as this—viz., 1882, 43.5°; 1846, 43.6°; and 1872, 43.6°.

The mean temperature of the six months from October, 1883, to March, 1884, was 44.2°, being 3° above the average of 113 years, there being six instances only of a temperature as warm or warmer—viz., 1819, 44.3°; 1882, 45.5°; 1834, 44.2°; 1846, 44.7°; 1849, 44.2°; and 1877, 44.6°.

AURICULA MRS. HORNER.

At page 328 a mistake occurs in the report of the National Auricula Society. Mrs. Horner, violet self Auricula, is stated to be raised by Mr. Turner; it is one of Mr. Horner's seedlings, and is, I think, a great improvement on any other in this colour. For many years Charles James Perry, raised by Mr. Turner, was the best flower in this class until a few years ago, when the variety Mrs. Douglas was raised and sent out by Mr. Simonite. This is a flower of greater substance than C. J. Perry, and holds a place in the winning collections. Mrs. Horner promises to be a better flower than either. The petals are what the fanciers term "rose-leaved," the pips flat and smooth, with a circular paste. Mr. Horner is the raiser of another very nice violet-blue, Sapphire by name; it is in several collections, and is very distinct; there is more blue in the composition of this flower than there is in any other. These new violet and violet-blue flowers quite do away with such varieties as Formosa (Smith), Metropolitan (Spalding), Meteor Flag (Lightbody), and others.—J. DOUGLAS.

[The error was a misprint not detected in time for correction last week.]

THE NAMES OF HARDY PLANTS.

IN answer to the note from "Specialist" on page 186 allow me to say that I fully understand that his motive in giving such a list was good, but I cannot agree with him, as my object would be to chronicle names which are purely synonymous, such as the plants have been described under by the various botanical authors. The following plant will well express my ideas on this point—viz., *Alyssum podolicum* (Besser), syn., *Schivereckia podolica* (Andrz.). It is left to our judgment which name to accept. If we desire to recognise very fine differences we are justified in acknowledging the plant as a *Schivereckia*. "Specialist" says he has kept a list of the different names under which he has received common plants, and no doubt he knows which is the correct name. When we receive a plant under a wrong name, and we are anxious that it should be distributed under its right one, the best course would be to convince the sender of his error. This proves a hard task sometimes, but it is one of the safe methods to lessen the much-felt inaccurate naming of plants, and I am sure that all reasonable persons would gladly welcome such an intimation. If we know a plant thoroughly the difficulty of convincing individuals of an inaccuracy is much reduced.

The pseudo names mentioned by "Specialist" I consider very misleading in many cases; for instance, *Eupatorium sessilifolium*. We may almost infer that if we write to a firm for this plant we may expect to get *E. ageratoides*; and further, I suppose if I already possess *E. ageratoides* I need not trouble about getting *E. sessilifolium*, for if I procured such it would only tend to extend my duplicate collection instead of adding another species to my list. These two plants I presume are not very generally in cultivation, but they are so distinct from each other specifically, that if we once become acquainted with them we ought never to forget their differences. *E. sessilifolium* has somewhat narrow lanceolate leaves, sessile, 4 to 5 or more inches in length, 1 to 1½ inch broad, and rather irregularly but sharply serrated. Flowers white, in large rather lax terminal corymbs. *Eupatorium ageratoides* has heart-shaped leaves coarsely serrated, about 4 inches in length and 3 inches in diameter, with a stem (petiole) 1 to 1½ inch long. Flowers white, in large terminal corymbs; the clusters of flower-heads forming the inflorescence are more compact than those of *sessilifolium*. The above two plants, which are almost as distinct from each other as regards their leaves, have been growing at Kew, and undoubtedly correctly named.

"Specialist" asks me to point out the differences between *Campanula lamiifolia* and *C. alliariaefolia*, dealing with the plants as they exist under cultivation. *C. lamiifolia* I do not grow now, but I have had it. It is considerably dwarfer than *C. alliariaefolia*, and with the stems much branched. The flowers, which are a yellowish colour, are invariably secund, and almost as pendent as those of *C. Van Houttei*, but only about an inch in length. The leaves are broadly heart-shaped—indeed, the width materially exceeds the length, and may be described as reniform-cordate, with doubly crenate margins, supported on petioles 1½ to 2 or more inches in length. The upper leaves gradually diminish in size and in the length of their petioles, but the prominent doubly crenate margins are always present. The leaves, I may add, are decidedly thicker than those of *alliariaefolia* and copiously tomentose beneath, as also are the branches throughout the whole plant. *C. alliariaefolia* grows almost twice the height of *C. lamiifolia*, the inflorescence is not so secund, neither are the flowers so pendent. The leaves are narrower in proportion to their length, their margins are not crenated but are finely serrated, the upper leaves are more decidedly sessile, longer in proportion to their width, and much more taper-pointed than those of *C. lamiifolia*; also the leaves throughout the whole plant are thinner in texture, and only very slightly tomentose.

With reference to the *Androsaces*, it may be well to note that I have grown both species—*A. lactiflora* or *coronopifolia* and *A. septentrionalis*. They are of annual or biennial duration. *A. septentrionalis*, if allowed to have its freedom, will, if in a suitable place, come up as spontaneously as a weed, and it appears to me feasible that the plants at Kew have cast their seeds behind the label of *A. lactiflora* and taken possession of the place. It is a plant likely to crush out the less flexible-constituted *A. lactiflora*. The leaves of both are very similar in outline, but *A. lactiflora* makes much the larger rosettes. The stem supporting the central umbel is quite erect, the surrounding ones bow outwards from the base, and then gradually curve inwards, displaying a bow-like peduncle. This character is anything but conspicuous in *A. septentrionalis*, which makes a rosette of leaves much smaller than *A. lactiflora*. Also *A. lactiflora* has larger umbels, and the individual flowers are much larger, and hence more conspicuous than those of *A. septentrionalis*.—PRACTICAL.

RHODODENDRONS AT DAYLESFORD.

IN your number for April 10th, page 283, mention is made of a remarkably fine specimen of *Rhododendron Nuttallii*, now growing at Daylesford, but nothing is said of the history of the plant. Is it known by whom it was introduced? Is it possible that it is one of the rare India plants brought there by Warren Hastings, who bought Daylesford in 1788, and took exceeding pains with the gardens? He certainly collected plants from the Himalayas, and sent an envoy on one occasion close to the Sikkim district, which I believe was not again visited by any Englishman for many years.

In 1774 Warren Hastings sent Mr. Boyle to Thibet on a mission to the Teshu Lama, hoping to open up trade with the country, and Boyle passed through the Himalayas, close to Sikkim. Among the private commissions given to Boyle by Warren Hastings he was told to send any curious or valuable seeds or plants, and any curiosities, whether natural productions, manufactures, or what else might be acceptable to persons of taste in England.—H. W.

HARDY FRUIT GARDEN.

Peaches and Nectarines.—Notwithstanding the cold weather the fruit of Peaches and Nectarines have set fairly well, and are slowly swelling. The outer foliage of most of the trees is sadly blistered by the cutting north-east winds, and no shoots will be removed until the weather becomes warmer. Under the most favourable circumstances we never begin disbudding until the fruit is set and swelling freely, and in so ungenial a

spring we shall be more deliberate than usual, both for the sake of the fruit, and also because the prominent foreright shoots screen the other shoots in some degree from cold and blister. As the weather softens remove protecting netting or screens, so that the foliage may have the full benefit of light and air, and may by such safe exposure become better able to withstand the effects of any subsequent recurrence of harsh cold weather.

Shelter.—Never was there a spring when the importance of shelter and situation was more fully exemplified than the present one, and now is the time to mark any deficiency in either of them, and to decide upon such remedial measures for next planting season as may be possible. It is the trees in damp low-lying and exposed situations that have suffered most lately, while those upon higher slopes or with thorough wind screens have passed through the trying ordeal with comparative impunity. A row or two of tall trees around a fruit garden may serve to break the force of the wind somewhat, but several rows are requisite to do it effectively, and even that is insufficient for a large fruit garden, which should have intersecting hedges about 60 feet apart. We cannot too often call attention to the value of *Thuia Lobbi* for this purpose.

Hellebore Powder.—A powder made from the root of the White Hellebore (*Veratrum album*) is now in general use for the destruction of the sawfly caterpillar, which eats the leaves of the Gooseberry and Red Currant. It is shaken over the foliage, and undoubtedly kills this troublesome pest, but it is a deadly poison and can hardly be used with safety among bushes where the green fruit is likely to be picked. We prefer to avoid the risk and practise hand-picking and smashing the caterpillars. A boy will look over all the bushes of most gardens in a few hours, and if taken in time they are easily kept under.

Strawberries.—The dry weather has been favourable for keeping down weeds, which come freely now between the rows of Strawberry beds. Do not put litter between the rows till the fruit is swelling, in order that the beds may be left as free from weeds as possible during the fruiting season, and that sewage may be applied as long as possible.

FRUIT-FORCING.

VINES.—*Early Houses.*—Early Grapes now ripening will require moderate fire heat to keep up a circulation of air, rather dry and warm by day, allowing it to fall to about 60° at night. Although a somewhat dry atmosphere is advisable when Grapes are ripening, excessive dryness must be guarded against, as this will seriously affect the foliage, and early Vines with ripe fruit will need considerably more water than late ones; and it is absolutely essential to keep the foliage of early Vines in good condition as long as possible, so as to prevent too early maturity, and consequently early rest and constant starting into growth a second time long before it is considered expedient. In order to prevent too early ripening of the foliage, not only keep the soil moist, but allow as far as practicable a moderate extension of lateral growth, and this in combination with the shade thereby secured will insure the fruit keeping on the Vines in much better condition, there being no fear of damage to early Grapes from moisture providing the house be freely ventilated. Gradually remove the spent fermenting material on outside borders, leaving a good mulching as a protection for the surface roots, and the summer rains will wash down the properties of the manure, stimulating surface-rooting, which in its turn will induce the production of lateral growth, and so prevent premature ripening of the foliage.

Midseason Houses.—The Vines in these have set their fruit and have been thinned. Those that are swelling should be well supplied with tepid liquid manure, and, to encourage surface roots and roots from the collar, should be well mulched with short partially decayed manure and kept moist, but the damping of the mulching material must not be given in lieu of periodical saturations of the border, which should be given as occasion requires, so as to pass the drainage. Allow a moderate extension of lateral growths, always being careful not to allow them to crowd the principal foliage, but where the roof is covered evenly with foliage, and there is not room for extension without crowding the principal foliage, keep it closely stopped. Avoid overcropping as the most fatal to good finish, and if there be any doubt about the crop being too heavy for the Vines to finish satisfactorily, give the Vines the benefit at once by removing the surplus bunches. The houses should be ventilated in good time in the morning, give a little early so as to allow of accumulated moisture being dissipated before the sun acts powerfully on the foliage. Begin to ventilate rather freely when the temperature is 75°, and keep it through the day at 80° to 85°, closing at the latter with a thorough damping of available surfaces at the same time, and after being closed a few hours a little air may be given for a short time, and the temperature allowed gradually to decline, so that 65° or 60° is recorded through the night, a low night temperature being very much better than a high one.

Muscats and others of a similar character that have just set their fruit will require careful thinning as soon as the properly fertilised berries take the lead. If more bunches have been left until after flowering than will not be required for the crop—a common and bad practice—no time ought to be lost in removing them, as there are no Grapes that show so greatly the effects of an overcrop as Muscats. They may swell right enough, but they never colour well. Muscats are also gross feeders even for Vines, and must have abundant supplies of tepid liquid manure with heavy mulchings, and the lateral growth should be allowed to extend as far as space admits. This must not be carried too far, as light is absolutely essential for the principal wood and foliage, also for the fruit of this particular Grape, as it seldom colours perfectly beneath densely crowded foliage. Early Muscats are sometimes scorched at this time of year when the sun is

powerful, which can, however, be prevented by maintaining a rather warm freely ventilated atmosphere, or a little constantly, particularly in the early part of the day. Where these Grapes are beginning to colour maintain a circulation of rather dry warm air through the house constantly, and a temperature through the day of from 80° to 90°, or 95°, and 70° to 75° at night if the ripening is to be accelerated, but they will ripen more evenly if allowed a little more time, affording rest at night by allowing the temperature to fall to 65°.

Late Houses.—The Vines have made rapid growth of late, although as a rule they have started weakly this season, and there is a tendency to form loose bunches or to run into tendrils. This is invariably a consequence of unripened wood, due to the practice of reserving fire heat in spring instead of having the Vines forward to admit of their receiving the full benefit of the summer sun, for to grow late Grapes well they require a long season of growth, and need more time to ripen than other Grapes. Vines that exhibit the tendency to run into tendrils should be kept somewhat drier, bringing the shoots down to the wires and stopping to within two or three eyes of the fruit, the best time to do this being in the afternoon of fine days when the growths are somewhat soft. Close early, making the most of sun heat.

Vines in Pots.—Give these every encouragement to make clean short-jointed growth by training them near to the glass, and ventilate freely on all favourable occasions, so as to insure thick leathery foliage, so that the eyes at their base may be properly developed, which they never do when their leaves are thin and flabby. Stop the laterals at the first joint, afterwards allow them to extend; they may depend or otherwise, only they must not in any case interfere with the access of light to the principal leaves and canes. Stop the main shoot or cane when about 8 feet long, and allow less lateral extension at the upper part than at the base. If there is convenience Vines from eyes or cut-backs intended for early work next season may be planted out in narrow prepared borders, and these will give much better returns than those grown exclusively in pots. They should be planted at about 2 feet 6 inches distance apart; a span-roof house about 12 feet wide will accommodate a row of plants on each side, the bed not needing to be either wide or deep. Where late spring planting is contemplated it should be attended to at once, as the stronger the canes the more certain are they to fruit, neither Grapes nor clean short-jointed wood being had from half-ripened wood, the encouraging of late growth in young canes being anything but furthering of a satisfactory growth another season.

Melons.—Where the fruit is ripening it is necessary to maintain a drier and more airy atmosphere in order to insure good-flavoured fruit; consequently a little air should be left on at night, as a confined atmosphere is a cause of cracking, and deteriorates the quality of the fruit. Secure to succession houses a night temperature of 65° to 70°, admitting a little air at 75°, and add to it, but allow the temperature with the addition to advance to 85° or 90, and reduce it with the decline of the sun heat, closing the house for the day at between 3 and 4 P.M. with plenty of atmospheric moisture in the house.

In the case of plants in pits or frames add some more soil to the sides of the ridges or hillocks as the roots push through the soil, repeating as necessary until the allotted space is filled. Young plants ought not to become root-bound before they are planted out, for if they once become stunted they do not make free growth afterwards; hence if the position they are to occupy is not ready for them shift them into larger pots.

THE FLOWER GARDEN AND PLEASURE GROUND.

Propagation of Hardy Bedding Plants.—There are several hardy or nearly hardy plants that are very serviceable and effective in summer bedding arrangements. Included among these are *Festuca glauca* and *Dactylis glomerata variegata*, two very pretty Grasses; *Golden Thyme*, very pretty when well coloured and in a small state; *Polemonium caeruleum variegatum*, creamy variegation and good for clumps or inner lines; *Veronica incana*, *Cerastium tomentosum*, *Antennaria*, *Sedum glaucum*, *S. acre elegans*, all dwarf carpeting sorts with white or greyish foliage; *Sedum Lydium*, *Mentha Pulegium gibraltaria*, *Herniaria glabra*, close-growing green carpeting plants; *Stellaria graminea*, *Spergula pilifera aurea*, golden carpeting plants, the latter moss-like and extremely pretty; and *Ajuga reptans*, purple leaves, dwarf-growing. All may be freely divided, and every small piece with a few roots attached, if dibbled in rather thickly in good light garden soil and watered they will become strong and well rooted by the time they are wanted for the flower garden. The carpeting sorts, such as *Sedums*, *Herniaria*, and *Mentha*, may be again divided prior to being permanently planted—in fact, they cover the ground more neatly if small pieces are dibbled in thickly, rather than planting in larger patches. *Polemonium caeruleum var.* is rather slow-growing, and the side shoots of these are best taken off with a few roots attached, potted off singly in 3-inch pots, and placed in a cold frame till established. The fruit borders or any convenient places in the kitchen garden will do for all the rest of the above-mentioned plants.

Dahlias.—Where these were started in a cold house or frame they will now be sufficiently advanced to admit of their being increased either by cuttings or division. The former are best taken off with a heel, and when about 4 inches long placed singly in the centre of 3-inch pots filled with sandy soil and placed in a rather close dry heat till rooted. Cuttings will strike without a heel, but not if the stem be hollow. The old stools or crowns may be cut into several pieces, or as many as can be had with a single growth and tuber attached. Pot them singly into whatever size pot they can be comfortably placed, fairly good soil being employed, and they should be arranged in a close frame until recovered somewhat, when they should be gradually hardened off. Seedlings in pans and in heat to

be placed in a cold frame, and in the course of a few days be potted off singly into 4-inch pots and kept growing in a cold frame till near the end of May, when they should be hardened prior to planting out.

Salvia patens.—This good old *Salvia* is perhaps the most effective tall-growing and blue-flowered plant we have. The cuttings may yet be taken and struck similarly to other softwooded plants. If the stools were started late in boxes of soil, they may be divided and treated as advised in the case of the Dahlias. The rooted cuttings are most readily transplanted from small pots.

Tuberous-rooted Begonias.—There are few better summer-bedding plants than these, and they are gradually becoming popular. Those who may wish to give them a trial are advised to purchase a number of dry bulbs at once from some respectable nurseryman who makes a speciality of them. Dry bulbs just received, or any not started already in the possession of our readers, should at once be taken in hand. Fill ordinary flat *Pelargonium* boxes with good soil, nothing being better than sifted leaf soil and loam in equal proportions, with a little sand added, and dispose the bulbs about 4 inches apart each way and just below the surface of the soil. Place them in a cold frame and allow them to grow slowly, gradually hardening them off by the end of May. In this manner sturdy well-rooted plants can be transplanted with a trowel into a necessarily rich border or bed without any check being experienced, and will eventually prove superior in every respect to any that may be started in small pots, and which are almost certain to become rootbound and starved. This year's seedlings, if transferred from the pans in which they were pricked out into boxes of good soil, kept in gentle heat till the middle of May, and then gradually hardened off, may prove serviceable; but as a rule they are much stronger and most effective the second year. The tops of strong plants started early may yet be rooted in heat, and these will form good bulbs for next year's display.

Hardening Bedding Plants.—Much of the space in the houses and pits will now be wanted for the more tender and quicker-growing kinds; consequently the more hardy, such as Zonal *Pelargoniums*, *Pyrethrums*, *Lobelias*, *Calceolarias*, *Gazanias*, *Violas*, and early-struck *Verbenas*, if still in a warm house, should at once be placed in cold frames or pits and hardened off. If they have been already partially exposed they may be shifted outside, but the change should not be too sudden, and some provision in the shape of a temporary framework and mats or curtains must be made for protecting the plants both from frosts and cold rains and wind. Such delicate plants as *Iresines*, *Coleuses*, *Alternantheras*, and *Heliotropes* must still be kept in rather warm quarters, as heavy rains and cold weather quickly damage them almost beyond recovery. Less water should at first be given when any of the above are transferred from warm to cooler quarters.

THE BEE-KEEPER.

VARIOUS PHENOMENA CONNECTED WITH BEES.

THE present time is perhaps the most interesting to the student and thoughtful bee-keeper, especially if his careful attention be directed towards the internal economy of the hive and the various phenomena found therein, to the activity and energy displayed by the bees outside in collecting honey, pollen, water, and propolis, and to the equal distribution of bees over honey and pollen-producing shrubs and trees. Any person of a reflective turn of mind watching this equal distribution of bees over flowers must be surprised. This phenomenon I have often tested when the bees were taken to the moors. When the first bees were let loose a clump of Thyme would immediately attract a certain number, working and gathering with a will from its numerous flowers, but it never became more crowded with bees even after the bees of other thirty hives were liberated. Nor is this all, a flower that one bee can rob of its nectar and pollen is seldom assailed at the same time by more than one bee. On the other hand, if flowers yield more than sufficient for one bee, two and more are frequently found working together. On the French Poppy, for example, which affords an ample morning's supply of pollen, I have observed a dozen bees in one flower at a time; on the Crocus, too, a profuse bearer of pollen, several bees may be observed at some time collecting and packing the golden-coloured pollen in large pellets. It is worth remarking that it is not at all times when the Crocus is in flower that it yields its pollen; the weather must be suitable ere its sheathed anthers containing the pollen open. There is another fact in relation to bees working on flowers that do not yield their pollen but at particular times. I have watched bees working on flowers for upwards of an hour without getting the slightest particle of pollen or honey. When this occurs bees are very liable to be lost, and is a warning to bee-keepers not to encourage them to seek during gloomy weather.

A very common occurrence at this season is finding queen cells being advanced, or it may be a premature swarm, which some people mistake for a natural one; or perhaps the old queen is found dead outside, and sometimes accompanied by young supernumerary ones.

The causes of this phenomenon are, the old queen may be effete (but often a perfectly healthy young fertile queen is so treated), intervening drone, and ragged combs are the cause; in short anything that interrupts the queen in the regular deposition of her eggs incites the young bees to raise queen cells. When such hives produce swarms it is seldom they become profitable the current season; so the better plan is to kill the young queens, return the swarm, and join a fertile queen to it or a weak stock. If the season and hives are so far advanced that drones are likely to be in abundance, a small nucleus or two may be formed, then these held in reserve may be utilised by joining to stocks after the issue of the first swarm. In fact one of the most important matters in connection with profitable bee-keeping is to have always on hand plenty of young fertilised queens from May until September, and the bee-keeper will find it much to his advantage if a young queen be placed at the head of every stock yearly.

My hives are made so that I can have either one or four nuclei in each. After the hive swarms and the young queens are piping I divide my frames into as many nuclei as is desirable, sometimes as many as twelve. If purity of breed or a particular cross is wanted they must be removed from the influence of objectionable drones, which ought to be at least five miles distant. I think that bee-keepers would be looking to their interests if they would study what are the best crosses. The best I have found are, first, a pure Cyprian queen crossed with an Italian drone, then the two in the next generation crossed with Carniolian drones. This year these crosses are far ahead of all the other, and last year both stocks and swarms exceeded in weight those that did not swarm. This present spring they worked at as low a temperature as 42°, of course not on flowers but on peameal.

While the foregoing notes point to the cause of premature swarming, I will now explain other phenomena with unsettled swarms and queen-encasements which occur, often giving trouble and anxiety to the bee-keeper, and very often resulting in the loss of the swarm. Unsettled swarms, or swarms that leave the hive after being hived, are caused first by a scarcity of meat at swarming time. To prevent this is to put the bees into a hive containing a little comb and feed liberally; a second cause is when the bees have fixed on a place to swarm beforehand, such as in a roof, tree, rack, or other crevice, or in an empty hive carelessly or wilfully left as a trap. Artificial swarming then is the best preventive. A third cause of leaving the hive is when stronger bees or an ejected queen from some other hive joins the swarm. In either case the bees will not settle, the queens are encased, and sometimes both are injured or killed, but often both are protected for some days, swarming several times daily during the delay and excitement. In such cases both queens should be searched for, caged, and the bees well sprinkled with very thin syrup scented with a little peppermint, then the desired queen may be joined to them. Such accidents occurring to swarms is sufficient for the bee-keeper to adopt artificial swarming, notwithstanding that what may be said in favour of natural swarming.

In making artificial swarms care should be taken that the old queen has not been superseded by a young unfertilised one (as described above), because, if so, both stock and swarm are likely to be ruined. In all cases of artificial swarming make sure that there are plenty of eggs and larvæ, and always leave as many bees as will rear and hatch these. If honey is scarce feed swarms liberally; and keep in mind, that though flowers are profuse at present, the yield of honey may be scanty—in fact, is seldom otherwise at this season. It is better to give each stock a few pounds of sugar to keep them advancing than to allow them to suffer. A little profit must be expected this season.—A LANARKSHIRE BEE-KEEPER.

SYRIAN BEES, LIGURIANS, &c.

"K. B. K.," (page 293), while saying "By all means let us face the truth," takes no pains whatever to do so, but bases his arguments on misquotations, and, what is worse, misrepresentations. Let us see. He quotes an article on page 132, vol. xx., of the *American Bee Journal*, and in it he would see a certain article is referred to page 38 by Mr. Benton, and one on page 500 for 1883 by the same writer. Anyone carefully reading these three articles will see that there are three distinct races of bees in question—namely, Syrian, Palestine, and Cyprian; and this "able bee-master" (Mr. Doolittle) calls the first two indiscriminately "Holy Land," and cannot tell one race from another, or by appearances from Italians; in fact there is no clear evidence that he has ever seen any Syrians or pure bees of either of the three races. In his letter on page 500 he gives reasons for doubting their purity as "Holy Lands." Then, "K. B. K.," to make matters worse, tries to show that some questionable Cyprians are Syrians, and talks about their stinging under the influence of smoke. In my letter on page 253 I said Syrians must not be smoked. I may say I have tried the Palestines, and do not want any more of them, because I cannot handle them with any comfort, as they are so fierce.

I do not care to notice "K. B. K." further for trying to face the truth in such a truthful way; but while I am on the subject I will say they are very much "befogged" in America regarding the pure races of bees, editors of bee journals being as bad as anyone. They call

Syrians and Palestines indiscriminately both "Holy Lands" and "Syrians." The editor of the *American Bee Journal* for April 2nd, page 218, ignores Palestines, and says all bees in America have come blacks, Italians, Cyprians, and Syrians, and no one seems able to tell any of the three races from Italians except when they sting, and this appears now to be their test for purity. Again, every bee-keeper there thinks there are no black bees in Italy, whilst as a matter of fact there are few others. Mr. S. Stutterd (one of the translators of Dzierzon's "Rational Bee-keeping") writes in the *British Bee Journal* for April 15th, page 140, that he has not been able to see a single Ligurian bee, even in Liguria itself, all being the ordinary black kind. What Ligurians (?) we get come from near the Alps, both in Switzerland and Italy, so give another instance of misnaming bees in America. *Apis dorsata* is known as "the great bee of Jarna," so Mr. Benton went to Jarna to get some, and found they did not exist there, but found them in Ceylon, thousands of miles away.

In reference to the letter of "A. Tyke" (page 293), I may state that the £20 profit on one hybrid stock of Syrians was made by the editor of the *British Bee Journal*, and will be found at page 127, vol. ix., and was made from swarms and honey only, and did not include a single queen sold or prize obtained on honey in twelve 2 lb. sections. The "£7" is a misprint, and should have been printed "seven"—viz., one stock increased seven, or one to eight, and is to be partly found in the *Journal* above named, page 145, vol. ix. The writer speaks of them as Syrians, but I have no difficulty in recognising them as "hybrids" from his account.

No doubt more information and hints as to management on these bees would be both interesting and profitable, and if space could be found I might try to do justice to the subject, quoting the experiences of some of the bee-keepers in Europe and America, as well as giving my own. When handled on a sunshiny day without smoke or jar the pure Syrians are tamer than the gentlest Ligurians. It must not be understood that I wish to condemn the blacks, nothing of the kind, they have stood their ground well, and are very good bees. My object is to improve them. Ligurians will not do it, the cross being vicious and addicted to robbing, and I think it is unreasonable to expect to improve a good bee with a worse.

I am obliged for information regarding the Blythe—or "Bligh"—should it not be?—competition. The rules do not provide for any distinction being made between the different races or cross of bees, though as "A. T." says, all are eligible simply as bees, therefore a young queen meeting with an undesirable mate could not be replaced by one which had, and so the different bees cannot be tested under the rules as at present drawn up.

I wish "J. P. S." on page 314 had taken a little care to try to understand the peculiarities of his Cyprians; for although I have not had sufficient experience with them yet to warrant me in giving an opinion, I do not think, however, they are as bad as some would make it out. All these eastern bees must be studied and managed according to their peculiarities. You might just as well expect to handle a black stock without smoke as Cyprians; and Syrians with it. "J. P. S." I should think, is confounding Syrians with Palestines from reading the *American bee papers*. If he will take the trouble to get a pure queen from Mount Lebanon, and have as many daughters reared from her mated with black drones as he can find strong stocks for, give them plenty of room and food to breed early in the spring, he will have plenty of supers filled from the Clover. To compare their working, storing, or wintering qualities with any other bees is like comparing Apples with Crabs. My favourites so far are the true Syrians from the Lebanon as sent by Mr. Frank Benton, who introduced them to bee-keepers, and is, I believe, the only exporter of them. Just to show the superior qualities of the first cross with blacks, in spring I shall find them very strong. I crowd them up, give them one or two quarts of thick syrup all at once (not a quarter pint of thin syrup every night through one pin-hole), which they quickly convert into brood, and by the time Apples are in bloom and all Nature looks gay they will have 14 square feet or 76,000 young brood, with twice that number of hatched-out bees. As they fill the frames solid with brood and keep it all in one compact mass there is no extracting from brood combs. I get a large early harvest (mostly my best) and could if I wished have three full stocks for the Clover, and all with less trouble than is usually bestowed on one, which is a great consideration even if I have proportionally no more honey.—HALLAMSHIRE.

TRADE CATALOGUES RECEIVED.

James Veitch & Sons, Chelsea.—*Catalogues of New Plants for 1884 (Illustrated), and Bedding Plants.*

* * All correspondence should be directed either to "THE EDITOR" or to "THE PUBLISHER." Letters addressed to Dr. Hogg or

members of the staff often remain unopened unavoidably. We request that no one will write privately to any of our correspondents, as doing so subjects them to unjustifiable trouble and expense.

Correspondents should not mix up on the same sheet questions relating to Gardening and those on Bee subjects, and should never send more than two or three questions at once. All articles intended for insertion should be written on one side of the paper only. We cannot reply to questions through the post, and we do not undertake to return rejected communications.

Royal Botanic Society's Schedules (A Reader).—These can be obtained on application to Mr. Coomber, Royal Botanic Gardens, Regent's Park, London, N.W., if there are any remaining for distribution.

Fruit Growers (J. C., Barnsley).—The subject on which you have written shall have our consideration.

Seedling Primrose (J. W.).—The flower, which was much withered, appears to be distinct and the variety worthy of preservation. Its peculiarity consists in the serration of the segments, giving the flowers a fringed appearance like the best varieties of *Primula sinensis*.

Preserving Dahlia Tubers (A. Gardiner).—Some of the Pompon and single varieties, especially when the plants are small, produce such small tubers that they are very liable to shrivel during the winter if kept too dry; at the same time, if they are too wet they will decay, while of course they must be kept from frost. There is no better plan of preserving tubers dug from the ground than to first dry them and then place them in boxes, covering the roots and crowns to the depth of an inch or two with a mixture of cocoa-nut fibre refuse and sawdust as nearly dry as possible, short of being "dry as dust," and keeping the boxes in a temperature between 40° and 50°. The reply to your question was in type last week, but crowded out in making up the pages.

Abroma augusta (L. U. G.).—In the paragraph on page 324 the specific name of the above plant was misprinted *angusta*, as you correctly observe, but your opinion that *angusta* means smooth is totally inaccurate. Consult a Latin dictionary. If you read the note again you will see that you have misunderstood the statement in reference to this matter.

Allium neapolitanum (C. U., Brixton).—This plant was figured in our issue of May 31st, 1883, page 451, and with it were given some cultural and descriptive notes. It is a native of south Europe, and though hardy in most parts of southern England, requires a warm border or cool house to insure its safety and success. In pots it thrives very well, needing a light, moderately rich, loamy compost, and plenty of drainage. Large quantities of the flowers are imported from the continent early in the season, and find a ready sale in the London markets.

Dioscorea Battatas (Pen and Ink).—This, the Chinese Yam, is, we presume, the kind to which you refer. We have grown it successfully in a sheltered garden in a southern county, and produced an abundant supply of tubers, but they were not enjoyed by many palates. The tubers were started in pots in a light moderately heated pit, much after the manner of starting Dahlias, and the Yams when established and growing freely were planted in a trench in which decayed vegetable matter, such as leaf soil, with which a little wood ashes were incorporated. Stakes were placed for the plants, up which they found their way after the manner of *Convolvulus*. Fine weather in June was chosen for planting, the tubers being placed in pots towards the end of April or early in May. Medium-sized whole tubers were chosen for planting, but the larger tubers no doubt might have been cut and planted in portions; we, however, did not try them, as we had always plenty of whole tubers. The other subject you mention shall have full consideration.

Recommending Garden Requisites (Financier).—It is quite impossible that we can do anything so invidious as to recommend the "best and most useful" article of any kind where there are so many that are equally good, but which may vary slightly in their action under particular circumstances. You can obtain lists of testimonials from vendors who advertise in our columns, and after a careful perusal of them you will not be very likely to err in the choice you may make. If we were to recommend the products of any firm as the best we should practically condemn all others unjustly, and this no one can properly expect us to do.

Cineraria maritima (H. E.).—Your plants are attacked by one of the leaf-mining insects, which it is extremely difficult to destroy without injuring the plants. We advise you to pick off all the worst leaves and burn them, and then proceed experimentally with a mixture of petroleum and water. We have seen the maggot in the leaves of Celery killed by syringing the plants with such mixture at the rate of 2 ozs. of the oil to a gallon of soapy water, and this did not injure the foliage; it was applied, however, in the evening, and the plants were shaded from the sun the next day. Had it been applied during a sunny day the plants would probably have been injured. We should try only half the quantity of petroleum at first for the *Cinerarias*, and note its effects on a few plants, before syringing them all. The oil and water must be incorporated as much as possible by violent agitation, as, if allowed to stand, the former will naturally float on the top. It mixes better in a solution of softsoap than in pure water.

Vine Laterals (H. S.).—You say the laterals on the original stem of your Madresfield Court Vine are only from 6 inches to 9 inches long, and showing bunches, but do not say how long the growths are on the other rods, which we presume are satisfactory. There is nothing remarkable in the bunches showing on laterals 6 inches long. Their mere length is of no moment, but their strength or weakness is a point of importance, and some of them may not be strong enough to carry the bunches that are showing. One bunch to each strong lateral is sufficient; and if the canes are short-jointed, and the laterals consequently close together, some of them should be removed. A suitable distance for them is about 15 inches apart along each side of the rods, as then the foliage has space for development; but if the growths are closer together it has not, and without good foliage you cannot have good Grapes. You say you find young canes produce the best bunches. This is generally the case, and does not this circumstance supply the answer relative

to the growths on the "middle" rod being weaker than the others? We suspect that rod to be older than the others, but you do not say so. Your other question will be answered in a future issue. Your address has been handed to the publisher. When business and editorial matter are mixed together confusion is certain to arise, as the two departments are distinct. You only sent stamps sufficient for four papers, and they will be sent to you.

Vine Leaves Curled (J. T. S.).—When bright sun suddenly occurs after several days of dull weather there is always great danger of the foliage scorching, as in the example you have sent. Assuming that the border is moist, you will do well to spread a little netting over any Vine that shows signs of flagging, this usually being a precursor to the curling of the leaves, or a sprinkling of limewash on the glass with a syringe has the same effect, and it is easily washed off again. You appear to have done right in damping the house, but you permitted the temperature to rise dangerously high, and your other Vines cannot but have had a narrow escape. Your night and fire heat temperatures are correct, but you must be particular in opening the top ventilators (slightly at first) very early in the morning, or half an hour at the most after the sun shines on the house.

Millipedes in Soil (R. B.).—As your "potting soil is full of millipedes" you must destroy them before using it. This you may do easily, and also render the soil more fertile by the process. The remedy is by baking it by placing it in trays and making it hot over a fire. With a brisk fire and an old tea-tray you may soon prepare a quantity of soil, which, however, must be sprinkled with water and made properly moist before using. You will be surprised to find how well all kinds of bulbous and softwooded plants will grow in soil that has been thus treated, while you will neither have worms nor millipedes in your flower pots. It is very difficult indeed to destroy these pests when they have found their way into bulbs. The safest of all remedies is lime water—a lump of lime as large as your hand with five or six gallons—and it should be applied in a perfectly clear state.

Woodlice in Mushroom Bed (W. B. G.).—If you cut Potatoes in halves and scoop out much of the inside of each portion and place them about the beds they will attract numbers of these insects, and they may be instantaneously, hence painlessly, killed by shaking them into boiling water. Boiled potatoes enveloped in a little hay and placed in empty flower pots and these laid on their sides prove enticing to woodlice, while pieces of parsnips boiled in an arsenical solution are deadly baits. We do not think you have much to fear from millipedes, which may be caught in a similar manner as woodlice. They have a partiality, however, for decayed matter, and do not object to a decaying Apple or bread smeared with treacle. If there are fissures at the sides of the bed the insects will congregate there, and boiling water poured in will prevent their coming out again, but it must not be sprinkled on the surface of the bed.

Repotting Ericas (W. W. W.).—The advice that was given in a recent issue not to attempt to liberate the roots from the soil when repotting applies equally to summer and winter-flowering Heaths. A little root-disturbance by removing the crocks, also by clearing away a portion of the loose surface soil, is all that should be permitted in transferring Ericas from small into larger pots, and even in those respects the work of liberating the roots must be done with great care and much caution. In potting these plants it is important that both the soil in which the roots are established, and that to be used is healthily moist. If either too wet or too dry success will not follow. The new soil must also be pressed as firmly round the roots as the old is, a blunted stick being used for that purpose. Many Ericas are spoiled by potting them too lightly and disturbing the roots needlessly.

Peas for August (Brevity).—It is utterly impossible for anyone to answer your question categorically, simply because no one can know the exact character of the weather you will experience during the season. The varieties named will probably need from fourteen to sixteen weeks from the time of sowing to the time of gathering, and you had better, therefore, sow a portion at once, and the remaining portion as soon as the plants from the first sowing appear through the surface of the ground. For producing large pods it is often advisable to sow in trenches prepared as for Celery, but with a greater depth of soil and manure, the surface of the rows after the seed is covered being 2 or 3 inches below the general level of the ground. Thin sowing is advantageous, or at least early thinning, as the plants will be quite close enough if they are 2 inches apart, two or three rows at the distance indicated being provided in each trench according to its width. Placing the sticks to the plants early is also of importance, as if the plants are suffered to fall over they seldom grow luxuriously afterwards. Grown in trenches any quantity of liquid manure can be given, and the finest Peas cannot be grown without it. The pods are also still finer if the plants are topped after four or five pairs of pods are set. If you want Peas for exhibition you had better top some when three pairs of pods are set, as you will then have the better chance of having fine pods at the time you need them. This is a matter, however, in which you must exercise judgment at the time, as no one can tell you exactly what to do two or three months hence.

Marechal Niel Rose Scorching (A. S. D.).—A tree so large in a border so small needs a very large quantity of water, and we have little doubt that the roots have been too dry, perhaps especially round the sides of the pit or border. A heavy dressing of soot, covering the surface of the soil an eighth of an inch thick, and watering it in with four gallons of tepid water, would be almost certain to have a beneficial effect, as would a similar application to your Jean Ducher, of course limiting the quantity of water to the requirements of the plant, erring, however, if you err at all, in giving too much than too little. Defective root-action, or, what amounts to the same thing, inadequate support, is one of the chief causes of the blooms not expanding. The glass of your house may have lens in it, and in this case light shading may be needed, and if so it should be given; but, generally speaking, healthy Roses well supported and growing in a well-ventilated house will endure full sun with impunity, even benefit.

Aphides on Lettuces (T. R.).—If the Lettuces are far advanced for use—that is, nearly ready for cutting, any deleterious applications would impair their quality. If the plants are young you may syringe them with a solution of softsoap, as you propose; but if they are of good size and the present leaves intended to be eaten, we know of no better method of eradi-

cating the insects than by syringing the plants with water heated to 120°. This will not injure them, while it will destroy many of the insects. If you have not a thermometer you may test the water with your hand; if you can endure its immersion for a quarter of a minute, but not longer, it will be hot enough to dispose of the green fly if it is forcibly applied on two or three consecutive evenings. Try its effects on a few plants at first, experimenting with half a dozen, also with water even a little hotter, and note the results the following evening. You will then find by experience how to proceed for destroying the insects without injuring the Lettuces.

Insects (J. G. M., Liverpool).—The specimens sent belong to the species of beetle called the bacon beetle (*Dermestes lardarius*), some being larvæ, others mature beetles. Their particular food is bacon and ham, hence the name, but they also devour skins and display cannibalistic tendencies. They would not meddle with any kind of fruit or vegetable. Where a colony of them have established themselves in a room there is no method of dealing with them except that of removing all that can be discovered, looking particularly into any cracks or nooks where the beetles might hide. To keep them out of any room a powerful odour is efficacious, such as the smell of paraffin or of a herb, such as Pennyroyal, dried.

Daisies on Lawns (Irish Subscriber).—There is no doubt about the value of household slops for applying to lawns; indeed, liquid manure of almost any kind is beneficial. We have recently inspected a lawn that has been immensely improved by being watered with the diluted drainings from a manure heap. The presence of Daisies in lawns is nearly always indicative of poverty of soil. An excellent dressing is a mixture of superphosphate of lime and nitrate of soda, two-thirds of the former and one-third of the latter applied during showery weather at the rate of 2 ozs. per square yard at intervals of a fortnight. If dry weather prevails it is a good plan to well water the lawn before applying the fertilisers, and then again afterwards to convey their virtues to the roots of the grass. Mixtures of guano and salt and soot and salt also act beneficially, so also do bonemeal and wood ashes. We mention these different ingredients in order that you may use what is the most convenient or readily obtainable. The most effectual mode of destroying Dandelions and Plantains is to drop a little sulphuric acid into the heart of each plant, as was recently recommended in these columns. Some persons have found lawn sand effectual in destroying Daisies.

Vines Scorched (X. Y. Z.).—The leaf sent is seriously scorched. The cause of this is the excessive transpiration of moisture from the foliage. Whenever this escapes more rapidly than it is supplied by the roots, first a slight flagging, then a shrivelling of the foliage follows. Vines growing so luxuriantly as yours appear to be doing need much water, often more than they receive; and you had better examine the border and ascertain whether the soil is moist or not quite to the drainage. They also need great care in ventilation, especially in the gradual admission of air very early in the morning. Although you do not quite close the house at night, we fear you do not always admit more air sufficiently early, or that you allow the temperature of the house to rise too high at times, and then throw open the ventilators too wide to reduce it. The size of the leaf and its thinness of texture leads us to the conclusion we have arrived at. It is certainly not such an example as a free-growing Vine would produce under a judicious system of ventilation of opening the lights at intervals in advance of the increasing temperature, and preventing its reaching its maximum by a rush. If we are mistaken in our opinion, and if the Vines have had sufficient water, and there has been no mistake in ventilating the house, then the only thing that can be done to prevent the collapse of the foliage is to slightly shade the Vines when a bright day occurs after a term of dull weather. It is often necessary to do this, and frequently shading is resorted to just after the injury is done. A little hexagon netting suffices, or a slight sprinkling of limewash on the glass. Shading Vines is, generally speaking, a measure to be avoided as far as possible, but it is decidedly preferable to scorched leaves. You say nothing about the temperature you maintain in the house.

Insects on Ferns (T. H.).—The pest is a small species of *Oniscus* or woodlouse, as you appear to have conjectured. They flourish in moist mild winters, and are apt to be very troublesome to a variety of plants during spring, especially those in pots. Trapping them is found to be the best plan of taking them, small pots being placed in their haunts filled with dry horse droppings, or preferably with slices of boiled potato or parsnip, which they will discover and swarm upon. They can then be shaken out into boiling water.

Name of Fruit (E. J.).—We have taken time to examine your Apple and to compare it with others, but are unable to determine its name. It is probably a local variety, of which there are hundreds that have never been authoritatively named.

Names of Plants (Somerset).—As near as we could ascertain from the crushed specimen received the tree is *Acer Pseudo-platanus*, or some variety of that species. (W. H. M.).—Specimen imperfect, but apparently it is *Euonymus europæus*. (J. G. M.).—*Doryopteris palmata*. (G. C.).—1, *Narcissus bicolor* Horsefieldi; 2 and 3, double varieties of *Narcissus Pseudonarcissus*. (T. B.).—1, *Begonia nigrescens*; 2, *Begonia odorata*; 3, not recognisable; 4, *Dendrobium densiflorum* album. (J. W. B.).—1, cannot be determined without flowers; 2, *Lygodium scandens*; 3, *Myrsiphyllum asparagoides*; 4, *Selaginella uncinata*; 5, The varieties of the ornamental-foliage *Begonias* are now so numerous that we cannot undertake to name them.

COVENT GARDEN MARKET.—APRIL 30TH.

No alteration in prices, but clearances more readily effected.

IMPROVING AND REGULATING THE SUPPLY OF FRESH BUTTER.

(Continued from page 336.)

IN continuation we will refer to the popular or customary mode of allowing or compelling the cows to go dry without yielding profit at all for a period of three months, more or less, in accordance with the time they are expected to calve again. To give an instance of the manner in accomplishing the object which we call unnatural, unprofitable, and afterwards attended frequently with serious results, we quote from an article published in the *Agricultural Gazette*, February 24th, 1884, by Mr. J. H. Walker, Worcester, Mass., in the United States, as follows—"Two months before a cow is due to calve every kind of food excepting dry hay, straw, and corn butts should be taken away from her, and only two quarts of water daily be given to her until she is dried off. Her milk should be drawn only once a day for two or three days. Milk every drop from the udder when any is taken. Rub and manipulate the udder very gently, just enough to prevent caking. Milk once in three days, then once in four or six. Dry as fast as it is safe. Some good cows will dry in one-fourth the time it takes to dry others. After you are sure the milk glands are dormant commence to give her, with her hay, dry oats. From that time until she calves give her only dry feed, hay, straw, corn butts, and oats, with roots or shorts enough to prevent constipation until she shows she is within a day or two of calving. From this time give a few potatoes or other cooling and relaxing food until she calves. After she calves give her a table-spoonful of nitre in warm water twice a day, or oftener if any fever appears, and feed very sparingly for a few days with relaxing drinks. Make haste slowly in getting her back on to hearty butter-producing food."

This perhaps may be one of the best methods which can be adopted for the purpose of drying or stopping the supply of milk, but the time here spoken of is limited to two months before the next calf is due. It is, however, the act of stopping the supply, whether it is two, three, or four months, of which we complain, for it is unnatural, because as wild animals like the white Chillingham cattle, would continue in milk without any interference at all except the spring of milk which would occur in the anticipation of another offspring. Again, it is unprofitable for the dairyman to lose ten or twelve weeks' produce of milk and butter out of twelve or thirteen months between the periods of calving, because feeding goes on although the returns of produce have been stopped. It is also serious, because it frequently happens that inflammation of the udder and puerperal fever set in after calving. Mr. Walker after advising dry food before calving, no doubt with the object of preventing any internal accumulation of fat in the cow; but he goes further, and advises nitre being given if fever appears, thus showing that it is commonly expected more or less when animals are dried of their milk prematurely, whereas it is by no means a natural result if the animals continue a milk record down to the period of calving. But these are not the only ill effects arising from shortening the milking period, because it is frequently attended with the loss of one or more teats by the caking or clogging of milk in the udder, especially in the case of great milkers; nor is it so easy, although Mr. Walker's system may be correct, to meet with men when in charge of and entrusted with the man-

agement of the cows to find them carefully and willingly carrying out the necessary orders.

There is yet another point to be considered, for in the system of drying cows of their milk prematurely in a dairy herd which are required to breed animals for maintaining the numbers of the dairy it is more than likely, that the short milking periods having been effected by compulsion, that future generations will also yield milk for short periods only, or in other words it will become hereditary, and the young stock succeeding prove capable of giving only a short supply of milk like that imposed and restricted in their dams. We will now hear what the advocates of the short milking period have to say in their own defence and in support of compelling the animals to cease yielding milk at any given period. They say that a continuation of the milking period up to the next calving time injures the constitution and reduces the quantity of milk for a certain period afterwards, at the same time weakening the calves when they come and reducing their size; at the same time they declare that the cows will not live so long in the herd if no period is allowed for them to be out of profit by prematurely drying of their milk. Supposing all these points are true in the practical management of a butter-making dairy, which we do not admit, still there can be no comparison between the advantages gained by the longest milking period and the freedom from losses which are traceable to cows having gone dry and accumulated fat internally, and by death through puerperal fever at calving time.

With respect to the profits of dairymen in butter-making, it is well to consider the disadvantageous results of the popular practice of having nearly all the cows to calve in the spring months and going dry in the autumn; for instead of any benefit accruing, the dairymen are positively not only acting against their own interests by having only a diminished quantity of butter to sell, but they are actually at war with each other by furnishing an over-supply in the summer months and reducing the selling price of their products at that period; and in the winter months, when the price it is not only at the highest, but in most cases actually unattainable at almost any price. This must be a serious loss to themselves, as it is also very difficult for the consumers to obtain supplies without resorting to the use of foreign imported butter, the quality of which in most instances is not only very unpalatable and nauseous, but positively injurious to the health of the class of people who must consume that article or none. This shows at least the way in which the dairymen's interests are sacrificed by their mismanagement in two ways—first, by shortening the milking period and having little or none to sell when the butter is in most request by their customers, and also by not regulating the supply throughout the year by having their cows to calve at all seasons of the year, instead of acting as now upon their own prejudices and the popular idea of having all their cows to calve in the spring. In some cases the dairymen attempt to justify their mode of proceedings by the argument that they seek to keep the cows in profit chiefly while the supply of grass is most abundant. This may be true in the grazing districts where the produce of the arable land is only to be obtained by purchase, or a portion of the grass produce cannot be secured in the silo as ensilage for use in the winter. But our previous remarks go to show that true economy in butter-making consists in furnishing and regulating the supply at all times of the year; and this is in fact the only way in which the butter-makers can benefit themselves by furnishing a supply in the winter months, which is now monopolised by the importers of foreign compounds of obnoxious ingredients. We consider the best policy in dairy management is not to allow the cows such short periods between their times of calving, but to extend the period by only taking a calf once in twelve or thirteen months, and continue the milking and butter-making during the whole interval between the calving periods, and feed the animals so that the last pound of butter should be as good as the first, which is the true commercial and practical view of the subject.

Let us see what records of milking have been substantiated both in America and on the continent. Mr. George Willis, in a paper read before the Nantwich Association, says, "I may tell you that I have seen in America a cow give 74 lbs. of milk in one day. I have also before me the milk records of some Holstein cattle kept at Little Falls in Western New York, showing that one cow six years old is credited with 84 lbs. of milk given in one day, 2360 lbs. in one month, and 18,004 lbs. in one year." Again, we find Mr. Jenkins, Secretary to the Royal Agricultural Society of England, speaking before the Farmers' Club in London said, "I know a farm in Denmark on which 220 cows have been kept for some years. On that farm there is no permanent grass land, and 220 cows are kept on arable land. I have myself seen a careful account of the yield of milk every day on these farms."

In the year 1841 a yield of butter on the average of 220 cows was 88½ lbs. per cow. But let me tell you that last year the average quantity of milk per head was 641 gallons; the yield of butter was 195 lbs. per cow against 88 lbs. forty years ago." These quotations are taken from the *Agricultural Gazette*, March 31st, 1884, and go far to show how great is the improvement to be made in a well-managed dairy, and at the same time shows that the custom of milking the cows for twelve months between the periods of calving is no new idea, but a well-recognised commercial method of management under the head of Dairy Farming.

After careful consideration of the subject we think that it seems strange dairymen do not as a rule test their cows by weighing the milk and butter product occasionally from each cow, in order that not only justice may be done in the feeding of valuable cows, but actually discarding as worthless those which show a low record of produce; and really in the selection of animals, although it is a question of judgment, it is at the same time a question of outlay by the purchase of superior animals. Again another matter crops up: Why keep more animals than can show a profit in products? for although superior animals may be costly, yet the lesser number eating the lesser quantity of food will yield a profit, when by retaining inferior animals in the herd it proves a loss all round. Great complaint comes to us from a statement at a meeting of the Blandford Farmers' Club in Dorset held in the first week of April, which county has long been celebrated for the sale of superior butter, both of fresh in summer and of well-preserved in winter. "Mr. George Galpin, a Dorset farmer, said there was likely to be a great falling off in the demand for Dorset butter in its present form in the London market. For some time past he had sent nearly all his butter there; but on inquiring the price in London last week a dealer told him that he did not want Dorset butter, as he could not sell it. The dealer in question showed him piles of boxes, each containing twelve 2-lb. lumps of foreign butter very nicely and carefully packed, which he was sure of selling, as it was all alike, whereas in the Dorset butter there was a great variation in colour and quality, the produce of no two dairies being alike." This shows that the butter got up in the factories abroad is all alike in colour, and probably oleo-margarine plays its part in insuring regularity of colour and flavour; when in Dorset butter any attempt to improve the quality by Channel Island cows introduced into the dairy and improved the quality by deepening the colour is rejected. This may prove a very serious and fatal blow to all pure butter manufactories in this county if the middlemen and butter salesmen are allowed to supply the market with foreign butter only.

WORK ON THE HOME FARM.

Horse Labour.—Horses are still employed in finishing off the land where the late sowing of drege has been concluded. It was, however, rather late for sowing, but the field is a cold strong piece of land, and the change from rain to the harsh east winds made it rather coarse and unkind for receiving the Clover and grass seeds for one year's lea; but after extra harrowing and rolling with the ring roller the seeding has been accomplished in fair condition by sowing after the ring roller, in which case these small Clover and grass fall into the grooves made by the rings of the roller, and then by the use of the chain harrows and a smooth roller to finish it off, both the drege and the grass seeds will be enabled to stand the effects of a dry summer, which in our changeable climate may or may not come. Still, some remarkable coincidences point in that direction, for we have not had a dry summer since 1874, years ago; and another remarkable coincidence we well remember, that every decade or tenth year since 1834 up to 1874 dry summers have prevailed, still we have had dry summers between these decades, but we find no similar succession of dry periods like those after searching the records. Whether the summer of 1884 will complete another decade time only will show, but one thing is certain, that we have no record of any cycle of nine years in succession when the Wheat crops of this kingdom have not exceeded the average until our last harvest completed the nine years of average or under-average Wheat crops. The season so far has been remarkably favourable for working and cleaning the land, not only for sowing Lent corn and planting Potatoes, but also for making an early preparation for the reception of the seeds of root crops, such as Mangolds, Carrots, Swedes, and all other early seedings for root crops. Still there is one thing to be kept in mind, that all our preparations should be carried on so as to make land safe in case of a dry summer by leaving the surfaces fine, which cannot be done with so little labour in any other way than by using power sufficient on the land to work it fine as fast as ploughing or scarifying is done. And the home farmer may feel assured that what is correct in the preparation of fallows for roots, &c., in a dry season is also the best practice in the event of a sudden change to a wet season. Where the land intended for Mangolds is fine on the surface the seed may be drilled on the flat with every prospect of the seed vegetating; still we do not object to the soaking of seed in water for two days previous to drilling. When there is a prospect and promise of dry

weather dunging with yard or box manure may be lost labour if we do not get a timely rain so far as the land is concerned, for the land not only becomes too dry whether the dung is laid under stretches or ploughed in on the level, but especially so on the stretch, because the throwing two furrows together to form the stretch and bury the dung brings all the driest and coarsest of the soil on the top of the stretch, which forms a bad seed bed. We therefore recommend drilling on the flat or level with artificial manures drilled with the seed, 3 cwt. of bone superphosphate, 2 cwt. of Peruvian guano, mixed with 1 cwt. of nitrate of soda, will prove a good dressing. If anything in the way of manure should be required nitrate of soda dressings at the time of first and second horse-hoings will be ample if 1½ cwt. each time is sown between the drills. One thing, however, may be borne in mind, that when the Mangold crop is intended to be removed from the land for cattle, we cannot very well have the land too highly manured, so that the Mangolds may not only yield the fullest crop, but the large amount of manure left in the land will come into operation for assisting the cereal crop to follow, whether of Wheat or other grain. Our first seeding for Mustard was done on the 12th of April, and two more seedings are to be made, the crops being each ploughed under with a deeper furrow every time, and the land ploughed and sown again the same day if possible on each occasion, so that the vegetating of the Mustard seed may be assured, which in the summer months is one of the principal points in cultivation for all root or green-manuring crops.

Hand Labour.—The hand-hoeing of early Peas should now be done, for the great art of effective hand-hoeing consists in cutting up the weeds in their infancy; for in case of showery weather if the weeds are strong they may soon become masters of the situation unless destroyed as soon as they show their second leaves. Our Peas are drilled at 12 inches between the lines, which gives just room enough for the hand-hoeing, and at this distance the Peas will soon spread and reach each other enough to keep down many or most of the weeds. Mixing the manures and placing them in bags ready for use often saves labour at important periods, such as haying; but in the case of nitrate of soda being mixed with other artificials, it should only be mixed on the day of drilling as fast as required for use, otherwise it may cake.

Live Stock.—The young cattle, both heifers and steers, may now be on the pastures grazing at daytime, and return to the yards and sheds at night time. The dairy cows, too, may graze on the pastures at daytime, but should not lie out until about the second week in the May month. In fact all stock which graze on the pastures should receive their oil cake or other allowance of feeding stuffs in the shed at morning and evening, or at the milking time for dairy cows. The home farmer in selecting dairy cows of any breed, whether for a cheese or butter-making dairy, should purchase or breed none but animals showing capacious udders and full-sized carcasses, shorthorns or Herefords for the former business, but Guernseys or Jerseys for the latter; but in some cases where the pasture is not very dry or first-rate half-breds, a cross from a shorthorned cow by a Guernsey bull, will furnish strong hardy animals especially adapted for a herd of considerable numbers. We make these observations because it is really painful to notice in various districts of small dairies near to inland towns the wretched and miserable nondescript cows which are kept frequently for the town milk supply. The season is now favourable for selling young sucking lambs, and if they reach 10 or 11 lbs. per quarter in weight they should be sold, for they will not be so much in demand further on in the season; besides which, the ewes if it is intended to feed them for the butcher, will be ready for sale sooner.

OUR LETTER BOX.

Mangold Wurtzels for Cow (Engineer).—By all means grow some Mangolds for your cow. You will find them extremely useful in the winter and spring when other green food is often very scarce. See cultural notes above.

REMARKS

20th.—Generally cloudy.
21st.—Bright early; two slight sprinkles of rain in morning, otherwise fine.
22nd.—Earthquake at 9.18 A.M.; fine, but two slight hail showers in morning.
23rd.—Fair, and some bright sunshine.
24th.—Fine morning; sprinkle of rain in afternoon, and shower at 5.30 P.M.
25th.—Fair, but not very bright.
26th.—Fine till about 5.30 P.M., rain afterwards.
A dry week, with N.E. winds, a small amount of cloud, and therefore large range of temperature, there being frost on the grass on every night but one, and even in the air on four consecutive nights.—G. J. SIMONS.

NOTES ON BROCCOLI.

NO difficulty was experienced during the past winter in supplying the table with an abundance of good Broccoli. Commencing long before the late autumn Cauliflowers were finished, they have hearted-in regularly—each sort in its own proper time—and will continue to be of service till early Cauliflowers are plentiful. It is not often that this happens, and recent immunities must not cause us to forget that Broccoli is by no means a certain crop unless it receives special treatment.

It appears to me that the two primary causes of failure are overcrowding and assigning the plants a loose rich soil. Each results in the formation of tall succulent growth, with stems that are much too long to be safe, as it is these long unclothed stems that are the most liable to injury, if not destruction, by severe frosts. If the plants are not killed the sap vessels are so damaged as to cause the largest and most promising of stems to form the smallest of hearts.

The two faults mentioned—viz., overcrowding and over-rich and loose soil—are not confined to the final planting, but are quite as often perpetrated in the seed beds. If the seeds of the early sorts are sown under glass, the seedlings should be thinned out before they spoil each other, and the first favourable opportunity should be taken of pricking them out on a fairly warm border and at such a distance apart as to admit of their transplanting with a trowel. The majority of Broccolis, however, are sown on sheltered borders, and there any of them can be raised quite as early as wanted, though not so surely, especially from old seeds, as when sown under glass. Unfortunately, warm borders are generally limited in extent, and as a consequence the seed is sown much too thickly. In addition the plants very often remain till they are drawn and, in fact, spoilt, as to start with tall plants is anything but a good preparation for severe wintry weather. Those, then, who sow thickly must thin out quickly and prick out the requisite number of plants. Those left in the seed beds will prove of service either in filling up any blanks or for giving away to less fortunate neighbours. As a matter of fact, an open poor piece of ground is the best place for rearing Broccoli, as well as Kales and Savoys, as in such a position, if the seed is sown thinly broadcast and covered with a little fine soil, or very thinly in drills and the soil levelled over them, a number of sturdy plants will be obtained, which during showery weather may be drawn and dibbled out without the loss of a plant. It is the overcrowded weakly plants that are the slowest to recover from the check experienced in the removal, and are thus much longer an easy prey to all pests that are liable to attack them.

Where the plantations shall be made has generally to depend upon circumstances. Few gardeners are able to entirely devote an open piece of ground to them, yet this is best if space could be spared. If planted among other crops they are almost certain to become drawn, while if planted in succession to them they seldom attain sufficient size and strength to be hardy and profitable. Supposing a quarter

has been occupied with Potatoes, Carrots, and other roots, if this can be devoted solely to Broccoli it is not advisable to either dig or manure the ground before planting. All that is necessary is to draw drills with a heavy hoe and to soak these drills either with water, or, better still, if at all poor, with liquid manure. This will admit of planting with a trowel, and which I prefer to cramping the roots into holes formed with a crowbar. If planted among Potatoes, the rows of these should be disposed at least 42 inches apart, unless they happen to be short-topped early sorts, when 3 feet is sufficient. When the Broccolis are planted between wide-disposed rows of Peas, which are, say, not less than 10 feet apart, not more than three rows of plants should be put out, and a distance of 30 inches be allowed between them in the rows. Even then they are apt to become much too tall.

We are obliged to double-crop as much as possible, and our plan is to plant the early varieties of Broccoli as well as late Cauliflowers between the rows of early and second early Potatoes, and the remainder either among main-crop Peas or in succession to early Peas, while the very latest sorts are generally planted on ground just cleared of Strawberries. Those among Potatoes, directly the latter are lifted, have a ridge of soil worked up to them with the spade, this serving to steady as well as protecting them to a certain extent. Instead of arranging the Peas at wide intervals, we prefer to have the rows about 7 feet apart, and to plant a single row of Broccoli between them. In this case the plants are only 18 inches asunder, and alternating on each side of the line, so that half are disposed to fall one way and half the other. The Peas, however, tend to draw them up, and in order to protect the moderately long stems early in November the soil on each side is well mounded up to the heads, this both improving the soil and saving the Broccoli. They are generally cleared off in time for the quarter to be planted with Potatoes or sown with root crops. Those planted on the undug and very firm Strawberry ground are invariably the sturdiest and the hardiest plants; in fact I have seen these only escape when all others not earthed up or otherwise protected have been destroyed.

Lifting the plants and laying them in the ground up to the leaves no doubt frequently saves the crops, but it also materially reduces the size of the heads. So also does laying without lifting, and both are laborious operations. As I have previously intimated, many of us are too greedy—that is to say, we put out too many plants instead of being contented with fewer, which would be more likely to escape destruction by frosts. If market growers find it advisable to dispose Broccoli plants 3 feet apart each way, and that too in the open and not very rich fields, how much more necessity is there for those managing sheltered rich gardens to allow plenty of space. On loose rich ground, then, I say make this as solid as possible; have the rows 3 feet apart and the plants not less than 30 inches asunder in the rows, while on firm or undug soil the rows may be 30 inches apart and the plants 2 feet asunder.

I have previously commented on the qualities of the different sorts of Broccoli, but shall venture a few more brief remarks on this portion of my subject. Veitch's Self-protecting again proved to be the most serviceable early sort, as both Walcheren and White Cape hearted too early to be valued. The former is nearly approaching to Cauliflowers, as it can be had early by sowing in the autumn and wintering in frames, or by sowing in heat in the spring, is very white and good in quality, and also unfortunately rather tender. The popular Snow's Winter White I used to sow early in frames, and never could understand why we secured so few good heads and so many monstrosities. Acting on Mr. R. Gilbert's advice I sowed much later, and on the open border, with the best of results. Mr. Gilbert recommends sowing early in May, but that is not early enough for our cold soil, and the middle of April best suits us. Those who are in the habit of sowing early and have previously partially failed

with Snow's, are advised to sow more seeds at once and note the result. We had Veitch's Spring White in succession to Snow's, and, though rather unfairly treated, from these we obtained some of our whitest and most appreciated Broccoli. It is not particularly hardy. The dwarf-growing Osborn's Winter White was again serviceable and good in quality, and this variety may safely be more thickly planted than some. Leamington is a great favourite with me; and this and Snow's as not being liable to turn in in large quantities at one time, thereby causing an undesirable glut, are the most extensively planted. The presumably latest varieties, such as Model, Wilcove's Improved, Late Queen, and Ledsham's Latest of All, are all turning in rapidly at this time (April 29th), and the latest will be a selection from Miller's Dwarf Late. Model is remarkably good in quality, and not much fault can be found with the other mentioned sorts. The old Cattell's Eclipse is still one of the best late varieties in cultivation.—W. IGGULDEN.

PRUNING DENDROBIUMS.

THERE appears to be much difference of opinion about the pruning of these plants, and, as far as I can gather from what has been written by the advocates of pruning, I think the ideas they intend to convey have been misunderstood. Only a few years ago I was much opposed to cutting away the spent pseudo-bulbs of these plants, but my ideas were then based only upon theory, and I refrained from writing upon the subject until I had proved the system. It is a great mistake to suppose that all Dendrobies are to be operated upon on the same principle, for such is not the case, and it has never been recommended anywhere as well as I can remember; but such notions have evidently become established, hence the communication of "G. W. C." on page 339 of your last issue. I do not think anyone would advise the pruning away of pseudo-bulbs of *D. thyrsiflorum*, *D. densiflorum*, *D. Farmeri*, *D. chrysotoxum*, and others of the same style of growth until they had satisfied themselves that if retained they would yield no more flowers. The length of time they continue to flower entirely depends upon how the plants are ripened after they have completed their growth. What is the object of retaining old stems after they cease to flower and are useless to the plant? The roots of these back growths, although they appear fresh, are dead, as will be found upon examination, in ninety-nine cases out of every hundred; but it has to be proved that they are not kept fresh and plump longer than they otherwise would be by supplies from the growing end. If the whole of these spent pseudo-bulbs are removed with their roots well syringed and supplied with water they will remain fresh and plump for a long time. It is evident that they have little or no force in them, or they would start into growth from some part, but do any of those named ever do so?

In passing, such species as *D. heterocarpum* should be examined that flower only on the pseudo-bulbs the second year after they are made. To cut these down like an herbaceous Phlox would be wrong, because the previous year's growth must be retained for flowering the following season; but those that have flowered, as far as I can form an opinion from practice and observation, are useless, and do not benefit the growths to be made. These old pseudo-bulbs will sometimes produce breaks along the stem, but will do this as freely when severed from the plant and laid or pegged upon moss as when retained upon the plant. When required for purposes of propagation they are much better removed.

I do not perceive much difference in the growth of pruned or unpruned plants of *D. Wardianum*, *D. crassinode*, *D. crystallinum*, and others that make an annual growth and flower upon it after being rested. I cut down a plant of *D. crassinode* that had not been pruned previously, and the growth up it now is just as forward and strong as those containing their old pseudo-bulbs. I shall more thoroughly test this pruning system this year than I have done in the past, for I do not believe there is any advantage to be gained by leaving the old stems upon the plants. If pruned plants possess no other advantage than an improved appearance it is worth practising for that alone.

Dendrobium nobile will flourish admirably under the most severe system of pruning practised by many growers. I can fully confirm what your correspondent "B." says respecting the flowering of *D. nobile* on the previous season's growth, but this is not due to pruning, as may be supposed, but to an early growth well ripened and thoroughly matured, which is the

secret of flowering this Orchid well without retaining two sets of pseudo-bulbs. The old stems if cut into lengths and placed in pots or pans will produce a number of growths, and form useful little plants the first season with sturdy pseudo-bulbs 9 inches or a foot in length. These after they are rested if started early will make good growths, which can be ripened early, and will flower profusely the same as the plant grown by "B."

Calanthes have been introduced into this subject, but they would have been better left out, for they prove nothing either for or against pruning *Dendrobies*, as they are entirely different. The old *Phajus grandifolius* might with advantage be introduced, as many people subject these to an annual system of pruning, for as soon as the young growths are seen issuing from the base the whole of the old foliage is cut clean away and the plants repotted. The plants subjected to this treatment are quite as strong and luxuriant, and flower as well as those treated on the opposite system by retaining the old foliage until it dies naturally.—SCIENTIA.

AËRIAL ROOTS ON VINES.

THE young rootlets which spring annually from the spurs of the Vine have occasioned much controversy amongst gardeners as regards the cause of their appearance. Some writers say the Vine house is kept too moist, others regard it as due to imperfect action at the roots. Experience with different Vine borders, varieties, &c., leads me to believe that it is neither of the above, but that it is more due to the variety of Vines and luxuriance of growth than to anything else. When I entered my present situation the Vines were far from being in a satisfactory state. They were very weak, having been overcropped; the roots were also at fault, being too far from the surface. These grievances, however, were gradually removed. The Vines were pruned and washed, as well as the houses, in the ordinary way; the outside borders were examined in the spring, adding fresh soil, lifting the roots nearer to the surface (those inside being done in the following season). This had a marked effect on the Vines, the young wood being nearly as thick again as the previous year's growth. It so happened that a considerable number of plants were grown in the vinery that season, such as Ferns and Camellias, which required much moisture, yet with the exception of a few aerial roots on a Mrs. Pince Vine not one was to be seen. The following spring the Vines commenced growing much more vigorously than they did the previous year, pushing out strong laterals with good bunches, everything doing as well as could be wished. Just as they were coming into flower they commenced producing aerial roots on the spurs, Gros Colman and Mrs. Pince varieties being the varieties affected that season. Last year they did the same.

This year particular attention has been paid to them. In the early vinery, which is 30 feet long, there are ten Vines growing. Beginning at the north end there is a Mrs. Pince and Black Alicante growing side by side. Mrs. Pince has aerial roots nearly on every spur, on the Alicante not one is to be seen. It so happens that at the other end of the vinery there is a Muscat of Alexandria which is emitting one or two rootlets, and they appear on the spurs that have the strongest laterals. Next to this Muscat is a Gros Colman Vine with large healthy foliage. Some of the leaves measure over 15 inches in diameter, the lateral growths being the thickness of one's thumb, and every spur has a cluster of aerial roots. Then comes a Black Alicante, the same as the one at the other end of the house, with no aerial roots. The other varieties are four Muscats and one Lady Downe's, resembling the Muscat already mentioned.

In another vinery there are seven Black Hamburgs, one Duke of Buccleuch, one Buckland Sweetwater, and another variety, supposed to be White Tokay. The fruit of the latter never gave satisfaction, but being a strong healthy Vine I did not like to pull it out, but inarched a Mrs. Pince on it (with the idea that it might colour better on this stock than on its own roots). This was done last year in June, as it made a fair good growth and ripened pretty well. It is now carrying two or three good bunches, and here on this young rod the aerial roots are now sprouting. Previous to this variety being introduced into this vinery I had never seen one of these roots. I should like to hear other Grape-growers' experience on this matter.—L. S. C.

TABLE-DECORATING.

THERE are few places now of any pretensions where indoor floral decorating does not form a very important part of a gardener's duties, and further, it may be said with a certain amount of truth, that it is carried out much more extensively and on a far more elaborate scale than it was a dozen or twenty years ago, and that during this comparatively brief period great improvements have been made. In all probability the decorating of the future will be as far in advance of the present as the present is over the past, and it behoves the rising generation of gardeners to devote some portion of their leisure to the study of this very important branch of their profession. No amount of reading will, however, alone make a good decorator, and with equal force it may be said neither will a good collection of plants or flowers. To excel in the art there must

be a natural taste and aptitude for the work. Many there are who with scant material at their command will accomplish far greater results in the way of pleasing combinations and telling effects than others will with a plentiful supply of the choicest and best flowers, and this, too, in a much shorter space of time. One great point in connection with our subject is, whatever work you are going to do, whether it be decorating a dinner-table, dressing an epergne, or furnishing a library or drawing-room, study well beforehand and contemplate the effect, so as to be able to picture to yourself the completion of your work before it is begun. By adopting some such rule as this many obstacles are easily overcome, and much time, together with material, such as plants and flowers, will be saved. When we have a definite object in view it is surprising how easily and quickly with a little tact and energy it may be accomplished.

Presuming we have a dinner-table to decorate on which cut flowers and leaves are to predominate, it becomes necessary to ascertain before cutting anything what ornaments in the nature of china, epergnes, glasses, &c., are available for our work. Having done this the tallest must be selected for positions down the middle of the table, and these are generally epergnes. In the dressing of these we cannot lay down any hard-and-fast rule, but there are certain practices to be avoided—viz., overcrowding and the opposite extreme. The principal object to be aimed at should be lightness, elegance, and gracefulness, a proper blending of colours, and a judicious use of Ferns, dried Grasses, sprays of climbers, &c. Fern fronds, although indispensable, should not be too liberally employed; moreover, it is always advisable to have them in character with the ornament in which they are put—i.e., the more bold and striking the latter so it should be with the Ferns. For instance, say we have an epergne or trumpet-shaped glass 2 feet high, we would make very little use of *Adiantum cuneatum*, much rather we should prefer *A. formosum* and other species of a like nature. A few dried Grasses are extremely useful for this kind of work, owing to their graceful appearance. Sprays of climbers for entwining round the supports of epergnes and hanging over the sides, *Ficus repens*, *Cissus discolor*, and *Ampelopsis Veitchii* are also very suitable.

Small globular glasses filled with Maidenhair Ferns and cut flowers should be arranged between the epergnes. In our opinion these look much better when one colour for each glass is employed than they do with two or three. Having placed all the ornaments containing flowers in their proper positions, the arrangement should be completed by laying on the cloth a line of *Selaginella*, this to extend the entire length and breadth of the table, and should be just inside the line of the knives and forks. Quadrants may be formed at each of the four corners, and it will add greatly to the effect if a row be arranged round the dessert dishes.

By way of a change (a very desirable matter in floral decorating) cut flowers may be employed in other ways different from that already described. In many places shallow tin troughs are in great request. These are made of various shapes and sizes, being 1 inch deep and about 2 inches in width. When they are arranged on the table so as to form geometrical figures and designs they have a most pleasing effect. Mounds of moss on circular boards dressed with flowers and Fern fronds are also much appreciated by many. Some little practice, however, is required to do them tastefully, and perhaps it would be for the benefit of the inexperienced to give further details on this point. For instance, say we have to make up a mound on a board 15 inches in diameter, we should first of all require a small well-grown plant of some kind, *Aralia Veitchii* or *Dracæna Cooperi* would do very well. This should be stood on an inverted 6-inch pot placed on the middle of the board, from the edge of the latter to the rim of the pot containing the plant fill in with fresh-gathered moss, which must have a gradual slope from top to bottom, and face with *Selaginella Kraussiana*. In this arrange the flowers, which should be in a continuous line the whole circumference, forming acute angles near the rim of the pot and 2 inches from the bottom of the board, a few Fern fronds to be intermixed here and there, the whole to be finished off with a row round the edge of the board about 6 inches long and resting on the cloth. Mounds of this description placed down the middle of the table have both a novel and picturesque appearance. Much more might be written on the subject, but as this note has already lengthened out into considerably more than was at first intended, further remarks must be left to another occasion.—ET CÆTERA.

THE GRASS GARDEN.

THE note I previously sent on this subject, and which you were good enough to publish, was confined to the consideration of flowers which blossom in the earlier portion of the year. While I at once concede that no flowers are so welcome, so pretty, and so much appreciated as spring flowers, I would not on that account limit the grass garden to spring flowers only. Yet while saying this, it must be admitted that the list

of plants suitable for growing on grass to flower in summer and autumn is short. Such plants must have, as a fundamental recommendation, the quality of taking care of themselves when once they are put out, a capacity for growing and flowering year after year without attention as to staking, thinning out, and transplanting, qualities which the majority of plants are altogether deficient of.

The Pampas Grass (*Gynerium argenteum*) may be named as typical of the kind of plant required. But we are not quite reduced to a sole dependance on this handsome Grass. There are a few others which might be introduced. The common Foxglove is one of the very best, and should be extensively planted close to the stems of shrubs. A packet of mixed seed sown now will produce hundreds of plants to blossom another year. The German Irises and the large-flowered pale blue *Iris pallida* are both well suited for culture in grass. Strong clumps dotted in the open is the best way of managing these.

A most effective foliage plant for extensive stretches of grass is the Giant Cow Parsnip (*Heracleum giganteum*). It grows to a height of 9 or 10 feet, and is best established in clumps of six to a dozen plants. Pheasants are said to be fond of the seeds. Sown now, and transplanted in autumn, these should be strong for another season. Tritomas make a glorious show of colour in late autumn, but unfortunately I have not found them succeed so well as we would think they ought to. It is worth while to prepare a bed, thoroughly cultivating the soil by working a 9-inch coating of manure into the ground, and after the plants are put out mulch the surface of the soil with more manure. If the beds are kept clean the first season, and an annual coating of manure, 4 to 6 inches in thickness, placed round the plants every winter, they will succeed in most places. After the first year the plants should grow enough to cover all bare ground.

Other good plants for employing singly which may be mentioned, are *Astilbe rivularis*, *Spiræa Aruncus* and *Spiræa venusta*, both herbaceous and tree *Pæonias*, *Lychnis chalcedonica*, *Lupinus polyphyllus* and varieties, *Aconitum lycoctonum*, *A. Napellus* and varieties. For covering stumps, the everlasting Sweet Pea, *Clematis Jackmanni* and Honeysuckle, *Clematis Vitalba*, Hop or climbing Roses are all suitable. By way of caution it may be added that it is very easy to overdo planting flowers on grass. As a rule they look much better, and indeed thrive better, in nooks in front of tall shrubs than in isolated positions with nothing round them but grass. When shrubs are small it is not only admissible, but a good arrangement, to plant flowering plants freely amongst them. But this and kindred matters I must leave for the present.—SYLVANUS.

WHAT IS AN AMATEUR?

MR. DODWELL appears to feel himself intensely maligned by a statement that has been made describing him as a nurseryman. But why he should be so irate is a question not easily determinable by unprejudiced people who are so constituted as to be able to calmly consider the whole matter. Is not the trade of a nurseryman an honourable calling? It is usually so considered, and several persons with whom I have spoken are simply astonished at Mr. Dodwell's conduct. The whole question appears to me to lie in a nutshell. Has or has not Mr. Dodwell issued a priced list of Carnations with the object of selling them? If he has done so, does not this constitute him a nurseryman? If it does not, what does? Is it necessary for a man to prove that he has made a profit by trading to be classed as a nurseryman? Assuming for the purpose of argument that Mr. Dodwell has sold Carnations to a very large extent, is he then properly eligible for competing in classes "for amateurs," and winning the lion's share of the prizes with flowers from what, if he publishes a priced catalogue, is to all intents and purposes a trade collection? These are questions of undoubted public importance, and the connection of Mr. Dodwell's name with them arises from the sheer necessity of the case, and it is certainly not mentioned now with the object of causing the slightest inconvenience to a person with whom I have never had the opportunity of speaking. Suppose we substitute the word "dealer" for "nurseryman," and I presume Mr. Dodwell will scarcely deny that he is a dealer, wherein is his position altered?—NEUTRAL.

SPRING FROSTS AND THEIR EFFECTS.

WE have clearly proved the value of even the slightest covering for fruit trees in a season like the present, ordinary tanned netting of 1-inch mesh (double), fastened to a coping standing slightly out from the wall, proving sufficient to preserve a fair crop of Peaches and Nectarines with the temperature at 22°. Another Peach wall, on which the top courses of brick recede from the line of wall, has suffered severely, it being a difficult matter in this case to keep the netting clear of the trees. Apricots, Cherries, Plums, and Pears are all gone. In a climate where such severe frost is possible during the spring months it is absolutely necessary that some protection should be at hand for all the last-named fruits, as well as for Peaches and Nectarines, that we may avoid the disaster of April 23rd. Where there are long stretches of wall it will be

necessary to devise the most economical covering possible, and with the view to attain this end I have thought of a piece of stout deal some 2 inches square firmly secured to the coping, on which again will be fastened an 11-inch board, either let into the first or nailed to it. The length of projection to the end of the board would, together with the 4½-inch coping, be about 16 inches, sufficient, I fancy, to keep the blinds clear of the trees. The tiffany, canvas, or whatever material was used, would be lightly tacked on the board some 2 inches from the edge. It would be used in lengths some 20 or 30 yards each, as this would enable it to be folded up under the board when not required, and thereby save the expense of pulleys, rollers, &c. Some hooked stakes would be thrust into the alley at a short distance from the wall and the canvas fastened to them when let down. That portion of canvas on and hanging over the board could be treated with oil or size and varnish to protect it from the weather; the blinds, and possibly the 11-inch board, would be removed when all danger was past.

Such is a rough idea for the protection of Pears, Apricots, Plums, Cherries, &c. I shall be glad if any of your readers who are already working anything likely to be an improvement on the same from a useful and economical point of view would give the benefit of their experience.

The morning of the 23rd ult. seems to have made sad havoc with vegetation generally, as well as the fruit crops. A large specimen of *Pterocarya caucasica*, perhaps about the finest in the country, is a total wreck; leaves, catkins, and the tiny leaflets just expanding are all black, and the foliage is decaying on the tree. Such old favourites as *Chimonanthus fragrans*, *Wistaria*, *Laurus*, *Sassafras*, and some of the *Magnolias* are nearly as bad. I am glad to say two members of the latter family we value (*glauca* and *macrophylla*) are safe, the sheath acting as a protection to the tender bud beneath.—E. B., *Claremont*.

THE effect of the very severe frosts experienced here on April 22nd and 23rd has proved most disastrous to the wall fruit in this neighbourhood, so much so that the Apricots and Plums are in many places entirely destroyed. The Damsons and Pears, which hitherto promised to be a very heavy crop, have shared a similar fate. In many cases the early-flowering varieties of Pears are completely destroyed; rarely, if ever, has the show of fruit blossom been more abundant.

Up to the present the Apples appear to have escaped injury, and should there be no more severe frost, the display of Apple blossom promises to be quite equal to that of last year. Thousands of trees throughout this county, which were so unusually heavily laden with fruit last season, are at the present moment covered with blossom buds.—H. R. I., *King's Acre, Hereford*.

THE severe frosts on the 23rd and 24th of April were most destructive here, as, the position being very sheltered, everything was much advanced, and consequently suffered severely. Apples and Pears will almost be a complete failure, the unexpanded blossoms of both being killed. Plums and Cherries are also killed. Examining some Quince blooms yesterday, although very backward, I find them quite destroyed. Pears on a west aspect, where slightly sheltered, perhaps one in a thousand Peaches, Nectarines, and Apricots are so far safe as my employer acceded to my request to put up glass coping, from the front of which was suspended scrim canvas, but where the canvas did not quite meet every fruit on the elongated spurs were more or less injured. Two Figs trees under the coping are safe; one unprotected, although in a sheltered position, is much injured, the points of the shoots being quite killed. Gooseberries, where the pruning had been severe, are a total failure; where left unpruned to defeat the frost and the birds, there is a fair crop in the centres of the bushes. Currants are also much injured with the exception of some trained on walls, north aspect. I do not think there will be a perfect bunch. The advantage of having efficient protection is clearly exemplified this season—the value of the crop of Peaches and Nectarines will almost pay the cost. Raspberries are much injured, but not to any great extent. Strawberries, fortunately, were not forward enough to receive damage. Altogether the fruit crop has suffered more than I ever experienced before.—J. GADD, *Belhus, Aveley*.

PRIMULA JAPONICA AT KEW.

BETTER grown examples of this fine *Primula* than those now flowering in the temperate house could not be desired; and if similar success was attained in most gardens this plant would soon become more popular. Mr. Binder, who is in charge of that department, has been very successful with it, having raised many hundreds of fine plants, and his system of treatment may be briefly recorded. The seeds are sown in August in light sandy soil, and the pots are placed in a cool frame, where they remain all the winter. In about eight months from the time of sowing the young seedlings appear, and as soon as large enough they are placed singly in small pots. A compost of leaf soil, good substantial loam, and one-eighth of well-decomposed cow or horse manure, is employed, and at subsequent pottings the plants are transferred into 48 or 32-size pots, being flowered in the latter. During the summer following the time of sowing extremely vigorous growth is made, and the plants now specially referred to attained the size of small Cabbages, the leaves of extraordinary size and substance. As winter approached these leaves gradually died, but the soil was not allowed to become dry, being kept in a moderately moist condition until growth commenced again in

early spring, and attention to this Mr. Binder considers an important matter.

The plants are now flowering, bearing spikes of four to six tiers of flowers, which vary slightly in depth of colouring, but are mostly of a rich shade of crimson. The leaves resemble large Lettuce leaves, but are more substantial, forming a fine rosette, which is a beautiful setting for the majestic spikes of bloom. Either for the decoration of the stages in a conservatory, or (as they are at Kew) plunged round the margins of the beds, they have an admirable appearance, and their utility cannot be overrated.—L. K.

HYBRID CYPRIPEDIUMS.

No genus of Orchids has submitted so readily to the efforts of the hybridiser as the singularly beautiful *Cypripediums*. Certainly much has been effected amongst the *Cattleyas*, but a far greater number of really distinct and handsome hybrids have been obtained from the *Lady's Slipper Orchids*. There appears to be scarcely any difficulty in securing almost any desired cross, and in the majority of cases the progeny present an exact combination of characters, which has been preserved even when the cross has been reversed. This was especially notable in the case of the beautiful *C. Sedeni*; the seedlings from both *C. Schlimii* and *C. longifolium*, fertilised with the other species, resulting in plants that possessed no characters to distinguish them from each other, except perhaps slight variations in colour. In, however, what may be termed secondary hybrids—namely, those resulting from crossing an established hybrid with one of its parents, some surprisingly distinct and beautiful forms have been obtained. Examples of this fact are again well shown by the offspring of *C. Sedeni*. For instance, *C. calurum* is from *C. Sedeni* and *C. longifolium*, and *C. cardinale* is from *C. Sedeni* and *C. Schlimii*, both very handsome *Cypripediums*, and, though partaking of the good qualities of the parent hybrid, are yet easily recognised. Again, by introducing another species we have a third gradation, as is shown in *C. Schroederæ* from *C. Sedeni* and *C. caudatum*, and *C. Ainsworthi* from *C. Sedeni* and *C. Roezlii*. Other examples of the same peculiarity might be given in the case of *C. Dominii*, but it is rather remarkable that there appears to have been no attempt to cross two hybrids.

The great advantage secured by hybridising in this as in several other genera is the greatly increased vigour and floriferousness of the plants so obtained, which has wonderfully added to the horticultural value of the plants. Some, indeed, are in bloom almost all the year round, and most readily cultivated in an ordinary style. The *C. Sedeni* group is especially remarkable for these qualities, and the bright rosy tint of the flowers, so distinct from most other forms of the genus, has still further increased the popular appreciation of these Orchids. So much success has attended the efforts of hybridisers in the direction of improving the growth, flowers, and general habit, that it is somewhat surprising some attempt has not been made to obtain a race of *Cypripediums* that would grow in cooler houses than those requisite for the majority. It would not, perhaps, be possible to cross such extremely divergent types as the ordinary hardy or North American *Lady's Slippers* with the tropical evergreen species, but the experiment would be worth trying. Then *C. insigne* has not been utilised sufficiently, for if the habit of this much-enduring useful Orchid could be combined with the handsome flowers of some others a race of incalculable value would be obtained that, in a gardener's point of view, would far surpass the others.

Undoubtedly there is still a wide field for fresh and meritorious productions in this genus, and it is highly probable that many distinct races will be yet forthcoming while we have such persevering and successful workers as Mr. Seden. By far the greater number of hybrid *Cypripediums* have been raised in Messrs. J. Veitch's nursery at Chelsea, first by Mr. Dominy, whose beautiful *C. Dominii*, *C. Harrisianum*, and *C. vexillarium* led the van of what has grown into a small army of forms. Mr. Seden has, however, paid special attention to this genus, and a large proportion of those enumerated in the list below owe their origin to his skill. As an example of one of the best of these, *C. grande*, of which a woodcut is given in fig. 86, deserves particular attention. This was raised from *C. Roezlii* fertilised with pollen from *C. caudatum* in 1875, but it has been thought that the latter was really the variety *roseum*, also known as *C. Warscewiczii*, at least such is Herr Reichenbach's verdict. It is a remarkably strong grower, producing rich green leaves 2 feet or more in length, the spike of flowers often exceeding these in height by a foot or more, and bearing several flowers. These have the narrow tapering petals of *C. caudatum* 12 inches long, of a delicate crimson hue, and fringed with dark hairs near the base. The dorsal sepal is yellowish, and the lip crimson spotted in white with a greenish tinge in the body. Plants have been shown at the leading metropolitan shows and honoured with first-class certificates.

Another very handsome and interesting hybrid, and one of the

most recent, is *C. Lceanum*, for which a certificate was awarded to Messrs. Veitch at the Royal Horticultural Society's meeting, Jan. 8th of the present year. In the production of this, the comparatively new *C. Spicerianum* has been employed with *C. insigne* Maulei, and it was a subject of common remark at the meeting in question that the hybrid was exactly intermediate in its characters. The dorsal sepal is much like *C. Spicerianum*, but with the purple spots of the other

at least 100 guineas, and it has been stated that the original purchasing price was 80 guineas. *C. albo-purpureum* is also very valuable; a good plant has realised 50 guineas, but a much larger and wonderfully handsome specimen has been priced at 150 guineas.

It is worth notice that the species most largely employed in raising these hybrids has been *C. barbatum* and its varieties, which have been concerned in the production of about a dozen or more, as several of

FIG. 86.—CYPRIPEDIUM GRANDE.

parent; the petals and staminode resemble *C. insigne* Maulei, while the lip is suggestive of the first-named species. But for the striking evidence afforded by this combination of characters some would have been inclined to doubt that *C. Spicerianum* was one of the parents, as it was thought it had not been in cultivation sufficiently long to obtain such strong plants from it.

Perhaps the most valuable of all the hybrids is *C. Schroederæ*, which is, I believe, represented by a unique specimen in the collection of Baron Schröder at Egham. This has been estimated to be worth

the Warnerian hybrids have probably been derived from that species with others. In nearly every case distinct species have formed the seed or pollen-bearing parents, but *C. marmorophyllum* and *C. patens* are both from *C. barbatum* with *C. Hookeræ*, the crossing being reversed. In the majority of these the *C. barbatum* influence can be clearly traced, and it is probably due to this that some have denounced hybrid *Cypripediums* as too much alike.

In the list given below all the hybrids are included respecting which any information could be gained, and it may be mentioned that

those of which it is stated that the parentage is unknown were raised by Mr. Warner at Chelmsford, but the particulars of the species concerned were lost.

Hybrids.	Parents.
C. Ainsworthii	C. Sedeni and C. Roezlii.
C. albo-purpureum	C. Schlimii and C. Dominii.
C. Arthuriatum	C. insigne and C. Fairrieatum.
C. Ashburtoniae	C. barbatum and C. insigne.
C. calanthum	C. biflorum and C. Lowii.
C. calophyllum	C. barbatum and C. venustum.
C. calurum	C. longifolium and C. Sedeni.
C. cardinale	C. Sedeni and C. Schlimii.
C. chloroneuron	C. venustum and C. Warneri.
C. conchiferum	C. Pearcei and C. Roezlii.
C. Crossianum	C. insigne and C. venustum.
C. discolor	Unknown.
C. Dominii	C. Pearcei and C. caudatum.
C. euryandrum	C. barbatum and C. Stonei.
C. gemmiferum	C. Hookerae and C. purpuratum.
C. grande	C. Roezlii and C. caudatum.
C. Harrisianum	C. barbatum and C. villosum.
C. Leeatum	C. insigne Maulei and C. Spicerianum.
C. lucidum	C. villosum and C. Lowii.
C. macropterum	C. Lowii and C. superbiens.
C. marmorophyllum	C. Hookerae and C. barbatum.
C. Marshallianum	C. venustum pardinum and C. concolor.
C. meirax	Unknown.
C. melanophthalmum	Unknown.
C. microchilum	C. niveum and C. Druryi.
C. Morganianum	C. superbiens and C. Stonei.
C. nitens	C. villosum and C. insigne Maulei.
C. oenanthum	C. Harrisianum and C. insigne Maulei.
C. patens	C. barbatum and C. Hookerae.
C. politum	Unknown.
C. porphyreum	C. Roezlii and C. Schlimii.
C. porphyrospilum	C. Lowii and C. Hookerae.
C. pycnopterum	C. venustum and C. Lowii.
C. Schröderæ	C. caudatum and C. Sedeni.
C. Sedeni	C. Schlimii and C. longifolium.
C. selligerum	C. barbatum and C. lævigatum.
C. stenophyllum	Unknown.
C. superciliare	C. barbatum and C. superbiens.
C. tessellatum	C. barbatum and C. concolor.
C. vernixium	C. Argus and C. villosum.
C. vexillarium	C. barbatum and C. Fairrieatum.
C. Williamsianum	Unknown.

As an indication of the respective ages of the hybrids above named, it may be mentioned that they were described in the "Gardeners' Year Book" for the following years, and were therefore either flowered or shown for the first time in the preceding year. 1870, C. Harrisianum; 1871, C. Dominii, C. vexillarium; 1872, C. Ashburtoniae; 1874, C. Crossianum, C. Sedeni; 1875, C. Arthuriatum; 1876, C. selligerum, C. tessellatum; 1877, C. marmorophyllum, C. oenanthum, C. pycnopterum, C. stenophyllum, C. superciliare, C. Swanianum; 1878, C. albo-purpureum; 1879, C. lucidum, C. nitens, C. patens, C. porphyreum; 1880, C. Ainsworthii, C. vernixium; 1881, C. Morganianum, C. porphyrospilum; 1882, C. calanthum, C. calophyllum, C. chloroneuron, C. conchiferum, C. gemmiferum, C. grande, C. meirax, C. melanophthalmum, C. politum; 1883, C. discolor, C. microchilum, C. Williamsianum; 1884, C. cardinale, C. macropterum, C. Schröderæ.

The structure of the Cypripedium flower is peculiar, and so distinct from the majority of Orchids that for the benefit of uninitiated readers a brief explanation may be given. In most Orchids the three sepals are distinct or easily traced; in the Cypripedium, however, the two lower ones are united, so that there appear to be only two. The lip, as is well known, is shaped like a pouch or old-fashioned slipper, and this form is very constant throughout the genus. At the centre of the flower is a peculiar organ, which varies in form from crescent shape to a triangular flattened shield-like body; this is termed the staminode, and occupies the place of the cap and pollen masses in other Orchids. There are two anthers or pollen masses, one at each side of the column, instead of at the top, and partly protected by the shield staminode. By dissecting a flower these characters will be readily perceived, and if anyone is desirous of entering the ranks of the hybridisers they will find no difficulty in doing so.—L. CASTLE.

expanded flowers respectively, or whether he includes all that he could count of undeveloped flowers and buds as well?"

— WE learn with much regret that M. JEAN VERSCHAFFELT, OF GHENT, died on the 20th of last month after a long illness. He was in his seventy-fourth year at the time of his death, and was greatly respected by all who had been brought into contact with him commercially or socially. His name was almost as well known in England as in Belgium, and many recognitions of the esteem in which he was held have been accorded him at various times.

— OF ORNAMENTAL VARIETIES OF PYRUS now flowering one, the most handsome, is P. Malus floribunda, which has large flowers, deep bright red in the bud, but brighter when fully expanded. P. coccinea is another good form, the buds being extremely bright, but the open flowers are lighter even than the preceding. P. Toringo is a curious variety, with diminutive flowers very freely produced, the buds being rich coral red. P. Pollveria has small silvery white leaves, and large cymes of white flowers; P. salicifolia being somewhat similar, but having, as the name implies, narrow Willow-like leaves.

— IT is announced that the BROCKHAM AMATEUR ROSE ASSOCIATION'S nineteenth annual Exhibition is fixed for July 7th, to be held in the grounds of Broome Park, Betchworth, on the invitation of Charles Dobson, Esq., and Mrs. Dobson.

— THE DOUBLE-FLOWED FURZE is now extremely attractive in many gardens, and when planted in suitable positions it cannot fail to be appreciated. On steep banks where little else would live it will thrive and flower abundantly, and on this account is especially valuable. We have seen carriage drives occasionally bordered with bold bands or hedges of this plant, and at this time of year these banks of rich golden flowers are unrivalled by any other garden shrubs for such a purpose.

— AS a curious instance of the variability of flowers under cultivation, an abnormal specimen of NARCISSUS INCOMPARABILIS SEMIPARTITUS in Mr. Ware's nursery is worthy of note. This variety usually has the cup deeply cut into six segments, corresponding with the divisions of the perianth (petals), but in the departure referred to both perianth and cup divisions are in fives, which, as our botanical readers will remember, is an unusual number in the monocotyledonous plants. The flower is otherwise perfect, not malformed in the slightest degree, and has a rather pretty appearance, the petals radiating very regularly from the centre. Some other irregularities are observable in the Daffodil quarters of the above nursery, but this is the most interesting.

— DIGGING IN SPRING.—We have received what appears to be a portion of an unfinished communication on this subject, or at least it contains neither name nor initials; and in the same envelope a lengthy series of notes, evidently taken at some trial when "John Wood's claim" was under examination, but who "John Wood" is or who our correspondent is, or whether the notes have been sent to us accidentally or not, we have no means of determining. Perhaps the writer of them, whose letter appears to have been posted at Otley, will communicate with us on the subject.

— AT a recent meeting of the Royal Botanic Society, Gardens, Regent's Park, held on Saturday, Mr. J. P. Gassiot (Vice-President) in the chair, Professor Bentley mentioned that in the last quarterly record of the Society was a note by the Secretary upon the fruiting in the Society's greenhouse of the COCOA PLANT. So far as he could ascertain, it was the only instance known in this country, and he was happy to say the fruit seemed likely to reach maturity and ripen its seeds. It was interesting from its being one of the very few plants that produced their flowers directly upon the main stem and large branches. The generic name "Theobroma" was given by Linnæus, and signified Food for the Gods; but it had not always been so regarded, for Belzoni, writing in the sixteenth century, said it was a drink more fit for pigs than men. Speaking of the consumption of cocoa, he said that the amount imported in 1820 was only a quarter million pounds, in 1866 it had reached four million pounds, in 1873 eight million pounds, and at the present time was probably not less than twelve million pounds per annum. Dr. A. Prior read a paper on the "Ginseng," a medicinal root highly prized by the Chinese.

— ABUNDANT evidence is forthcoming of the merits of ELLAM'S EARLY CABBAGE, for many gardeners have tried it with the utmost success. One of the best quarters we have seen is in the kitchen garden

"W." writes in reference to the paragraph (page 311) describing the CYCLAMENS AT STUMPERLOWE HALL—"Will 'W. K. W.' please state whether the specimens he referred to bore 500 and 300 fully

at Leigham Court, Streatham, where it has been grown with Early Battersea, and has proved much superior to the older variety. It forms neat compact hearts, which were ready for cutting in the middle of March, proving deliciously tender and good-flavoured. Not one has "bolted," the whole quarter of 200 or 300 being as even as possible. The Battersea samples are good, but much difficulty is now experienced in obtaining this variety true.

— FUMIGATING.—A correspondent ("E. A.") desires to know if there is anything as good as tobacco paper for fumigating, but cheaper. Our readers are quite at liberty to answer this question.

— THE HULL HORTICULTURAL EXHIBITION is to be held on July 2nd, 3rd, and 4th of the present year in the Botanic Gardens of that town. One hundred and five classes are enumerated for plants, fruit, and vegetables, the prizes ranging from £12 to 5s. In all the leading classes the prizes are very liberal; thus for ten stove and greenhouse plants in bloom and six fine-foliage plants, £12, £8, and £4 are offered; for eight varieties of fruit the prizes are £3, £2, and £1, and in others they are proportionately good. The Exhibition held last year gave promise of still further development under the same good management, and it is to be hoped that exhibitors will assist in rendering this Exhibition one of the best in the north of England, as the district is at present practically unrepresented.

— A CORRESPONDENT writes that "in North Warwickshire the FROST does not appear to have been very severe. Last year's Calceolarias are unhurt, and Petunias are not quite dead out of doors."

— "A. Y." considers *IBERIS GIBALTARICA HYBRIDA* "one of the most useful and showy hardy plants that have been introduced of late years, and its rosy-purple colour is very pleasing. It is very hardy, and succeeds well either in the open borders or on the rockwork. If seed is sown now in borders the plants will bloom well by this time next year."

— THE fourth annual Exhibition of the CARDIFF ROSE SOCIETY is announced to be held on Wednesday, July 2nd. The prizes, of which about a hundred are offered, vary in amount from £5 to 5s.

— HARDY FLOWERS IN AMERICA.—A correspondent writing from New Jersey, U.S.A., states that out-of-door plants are now growing most vigorously, and sends the following list of plants in bloom:—*Phlox amœna*, *Aubrietia olympica*, *Saxifraga virginica* pl., *Viola pedata* bicolor, *Houstonia cœrulea*, *H. rotundifolia*, *H. serpyllifolia*, *Galanthus Elwesii*, *G. Imperati*, *G. plicatus*, *Scilla siberica*, *S. bifolia*, *S. bifolia alba*, *Iris reticulata*, *I. persica*, *I. pavonia* (indoors), *Leontica altaica*, *Chionodoxa Lucilæ*, *Leucojum vernum*, *Thalictrum anemonioides* and its double var., *Adonis vernalis*, *Colchicum crociflorum*, *Trillium nivale*, *T. pusillum*, *T. sessiliflorum*, *T. grandiflorum*, *Helleborus* in great variety, *Puschkinia scilloides*, *P. sicula*, *Sisyrinchium grandiflorum*, Dog's-Tooth Violets, *Erythronium americanum*, *E. albidum*, *E. grandiflorum* and *E. propullans*, *Pyxidanthera barbatula*, *Corydalis Kolpakowskiana*, *C. Ledebouriana*, *C. cava albiflora*, *Sanguinaria canadensis*, *Anemone ranunculioides*, *A. nemorosa* fl.-pl., *A. bracteata*, *A. caroliniana*, *Tulipa turkestanica*, *Mertensia virginica*, and a host of Daffodils.

— CHOU DE BURGHLEY.—Mr. A. Harding writes:—"Last May with nine or ten other varieties of Broccoli and winter greens, I sowed a packet of the above new vegetable, and when ready four or five hundred plants were placed out in well-manured soil. The rows were 2 feet apart, and the plants 18 inches asunder. It was not till the first week in December that we began to use it, but from that time until the middle of April it was an excellent supplement to the other winter vegetables. When boiled for half an hour it is tender and has an agreeable flavour. The side sprouts also, after the main head has been cut, are better than the majority of spring greens. Like some others, my opinion last autumn was not very much in its favour, but I thought it too soon to either praise or condemn it; but since Christmas we have found it so useful that I intend to sow it again this year."

— WE have received the first part of "CASSELL'S POPULAR GARDENING," a new work, which is to be issued monthly, and to be completed in about twenty-four parts. It is to include a wide range of subjects, fruit, vegetable, and plant culture, designing new gardens, constructing houses, &c., and will no doubt form, when complete, a useful compendium of information relating to horticulture generally. The part

under notice contains chapters upon garden pots, ground operations, florists' flowers, the life history of plants, the kitchen garden, Rose culture, suburban gardening, and other subjects; but it may be noticed that the arrangement does not appear to be the most suitable for a work of this character. These chapters will be continued in subsequent parts, and when bound the reader will have to follow some subjects through a considerable portion of the work, an obvious disadvantage that will necessitate a bulky index. Had the dictionary form been adopted, and one subject concluded before another was commenced, it would have been far preferable.

— FROM the same firm we have also received the first parts of "THE BOOK OF HEALTH" and "CASSELL'S HOUSEHOLD GUIDE," the titles of which sufficiently explain their objects. The latter is an extremely useful work, quite an encyclopædia of information relating to home management.

— PARTS 2 and 3 of "THE ILLUSTRATED DICTIONARY OF GARDENING" (L. Upcott Gill, 170, Strand) continue the subjects from Allium to Apple in the same style as the first part previously mentioned. It is abundantly illustrated, several of the engravings being familiar catalogue cuts.

HELIOTROPES FOR WINTER FLOWERING.

FOR the successful flowering of Heliotropes in winter there should be a night temperature of 55° in order to secure a continuous growth, and if the plants occupy a light position each young shoot will terminate in a truss of flowers, and a long succession will be thus obtained; but if they do not occupy a light position, so that a certain amount of vigour and ripeness may be imparted to the new growth, the shoots will be weak, soft, and consequently flowerless. A shelf near the glass at the end or at the back of the house near the wall (if the house be a lean-to) will be a suitable position. During the summer the plants must have undergone a suitable preparation, therefore when the stock of Heliotropes is propagated for bedding in spring a few dozen of the most vigorous plants should be selected and grown specially for winter flowering.

They should not be allowed to become root-bound in small pots, but be shifted into a larger size before they receive any check, and as soon as all danger from frost is over they should be plunged in a bed of coal ashes up to the rim of the pots in the open air. All shoots must be pinched back to induce a bushy habit. The bed should occupy an open situation, and the plants must stand far enough apart individually to permit of a free circulation of air around them, thus insuring robust short-jointed growths. Such plants when placed on a shelf in a warm house in winter will produce a large number of flowers for cutting from October to February or March. Neat little bushes may be had in 5-inch pots, but the strongest will require a size larger. Plunging the pots in summer will save watering and prevent the hot sun acting so forcibly on the roots at the side of the pots, from which cause plants sometimes lose their leaves. All plants grown for winter flowering are better plunged in the open air in summer than placed on the north side of hedges or walls. It is a mistake to suppose the tops will be injured by bright sunshine if the roots be protected. This applies also to many other plants besides Heliotropes. A few of the most vigorous may if desired be trained as standards with stems 12 inches long. By attention to pinching good plants may be had in one season.

The dark purple-flowered varieties are the best for winter blooming, as the pale-coloured flowers become still paler in brisk heat, but the dark varieties still retain a delightful tint of purple, and are much prized. Heliotrope flowers may also be had in abundance in winter from old plants planted out and trained against a wall in a warm light house; indeed this is the best plan to adopt if the flowers are wanted in quantity. The plants should be pruned well back about the end of August, or a little later or earlier according to the time the flowers are required. The syringe should be used freely to induce a free and vigorous break, but when once the shoots are growing less syringing will be required, as this, when autumn is approaching, only tends to promote weak growth.

After a good break has been secured the size and number of the trusses of flowers will be in proportion to the direct light that reaches the plants, accompanied, as it should be, by a corresponding amount of heat. These are the two prime factors in the production of Heliotrope flowers in winter, and should always bear some relation to each other in forcing.—J. H. WALKER, *Hardwicke House Nottingham*.

TYING DOWN VINE SHOOT.—I wish to supplement the notes by "Vitis" on the above by advising young gardeners when tying down Vine shoots to train them at one angle, and at the final tying-down

place every shoot underneath the wires. This may seem a trivial matter to some, but it gives the Vines a neat appearance. It has another advantage, and that is, if the foliage is likely to touch the glass it may easily be lowered, when, if the shoot were over the wire, it could not be lowered.—A. YOUNG.

ROSE CHESHUNT HYBRID.

THIS is classed with the Tea-scented China Roses, and in my opinion it is one of the most useful we could have for outdoor culture. It comes into bloom about the end of May, and does not cease flowering until November. It has a splendid constitution, grows luxuriantly, and blossoms most profusely. These decided characters enhance its value considerably, as those who buy it, no matter whether they are skilled Rose-growers or not, may depend on it doing well and giving satisfaction in every way. It is not out of place amongst standard and dwarf Hybrid Perpetuals, and its massive handsome carmine blooms more resemble one of the best of these than any small Tea variety. It will soon cover a large space if planted against a wall, and I would recommend it as a Rose capable of doing good service everywhere out of doors. It is one of the best autumn bloomers I am acquainted with, and many fine blooms of it expand in October when the majority of Roses have ceased flowering.—J. MUIR.

THE NAMES OF HARDY PLANTS.

IN reply to the remarks of "Practical" (see page 350) with regard to the specific distinctions of the several plants he enumerates, and which were included by me in the list of garden names for hardy plants, perhaps I may be permitted to quote Mr. Wolley Dod's observations on the same subject with reference to the difficulty of arriving at any satisfactory understanding. As to the specific as distinguished from purely varietal character, he says, "It must be borne in mind that it is not practicable or convenient in horticulture to be limited to the use of botanical specific names," whilst admitting "that for specific types no more convenient standard could be adopted than that of the Kew Herbarium." It was with a view to the convenience of such a standard arrangement that I drew up a list of garden names, placing each under the species to which it should properly be referred, whilst mere varietal distinctions were not taken into consideration, although many of the names enumerated had been given to plants possessing minor characters of more or less value for garden purposes of distinction.

It will be obvious to "Practical" that in such a genus as *Campanula* a large number of the reduced names belong to plants which are unquestionably distinct in a varietal sense. Had my object been an enumeration of all the species and varieties of the different genera treated upon, a large number of these reduced names would have been retained for varieties or garden forms. I am ready to admit that under *C. alliariaefolia* a number of forms more or less distinct are included by botanists, and that *C. lamiifolia* is perhaps a good variety of the above species, although it cannot be said to be specifically distinct.

Cultivated plants often assume characters widely different from what would be met with in wild types in herbaria. Instances of this are of frequent occurrence in garden plants of long standing, and this assumption of what we may call a new character of plants under cultivation may perhaps account for "Practical's" *C. lamiifolia* differing so widely from what he knows as *C. alliariaefolia*. At Kew the difference between the two is so small that the plants are no longer looked upon as even distinct forms.

With regard to the generic name *Schivereckia*, I am at a loss to understand what is meant by "Practical" when he says that "it is left to our judgment" as to whether we shall accept the generic name *Alyssum* or *Schivereckia*. The "Genera Plantarum" places *Schivereckia* under *Alyssum*; and as the views of the authors of this work must be final, so far at least as genera are concerned, I do not see how it can be "left to our judgment" as to which of the two names should be adopted.—SPECIALIST.

VINE TRAINING AND PRUNING AT CASTLE COCH.

I HAVE much pleasure in answering some queries that have been sent to me from a correspondent respecting the treatment of the Vines in the vineyard at Castle Coch.

He asks first, "How many fruiting rods were tied up to stakes, and how many stakes are used, and in what manner are they arranged?" From three to four rods are allowed to grow from each Vine, and they are simply tied to the stake in the same "manner" that Raspberry canes are tied when trained to stakes.

He next asks, "How many bunches are left on each lateral, and how many buds are left above the bunch?" One bunch and sometimes two are left, according to the strength of the lateral, and the laterals are stopped at from six to seven buds or leaves above the fruit, so as to allow the canes to reach the top of the stake at the first stopping.

Then he asks, "Are the fruiting rods cut down close to the ground, so that the new rods spring from the root; or are they cut down to the last eye?" When the Vines are pruned they are cut down as close to the ground as possible, never leaving more than from two to three buds on the last year's cane; these are again reduced to one by disbudding. By this system of pruning the Vines naturally in course of time form stools like Osiers or Willows.

Lastly, he asks, "What is the reason Vines in vineyards are pruned on the long-rod system?" I should say the reason is because the cultivators

find that system to answer best, in the same way that the cultivators of the Vine around Paris find it answers best to cut the Vines down as close to the ground as possible.—A. PETTIGREW, *Castle Gardens, Cardiff*.

ORCHIDS AT WOOLTON WOOD.

THE most extensive collection of Orchids in the neighbourhood of Liverpool is that possessed by H. Gaskell, Esq. This collection is a very large and valuable one, and is still being increased by the addition of large numbers of species and varieties, and half a dozen houses are devoted to their growth. It is scarcely to be wondered that the love for Orchids is becoming so rapidly established, for a visit in the spring time to Woolton Wood could not fail to impress the most casual observer with the wonderful beauty and richness of the flowers of these plants. It is not my intention at the present time to enumerate the many fine plants of different species and varieties that occupy the houses, but to note the most conspicuous amongst those in bloom.

The *Cattleyas* first command attention, for some thirty or forty different varieties of that useful *C. Trianae* were in full beauty, and scarcely any two exactly alike, varying from the very lightest shades to those with dark lips of deep crimson or lake colour. *C. T. Backhousiana* stood out prominent amongst the others with its large rich-coloured lip. One of the Popayan varieties collected by the late Mr. Chesterton on his last journey, and flowering for the first time, rivals, if it does not surpass, that fine variety. The lip is of large size and well opened, and in colour rich crimson lake. The petals are large, beautifully feathered and veined down the centre with the same colour as that of the lip. This is the finest dark form of *C. Trianae* I have yet seen. Another form has pure white sepals and petals of great substance fully 6 inches in diameter, while the lip is over 2 inches across and of the darkest crimson, which is fringed with white nearly a quarter of an inch in depth. This variety possesses a peculiar fragrance, and will undoubtedly at no distant date receive a distinct name. Many light forms were noticeable, but these are not regarded with so much favour by Orchid enthusiasts as the darker ones, yet they have a delicacy and beauty that cannot fail to command attention. A noble plant of *C. Percivaliana* with twenty-four flowers was worthy of note; its richly marked yet peculiar-coloured throat renders it distinct and one of the most useful of *Cattleyas*, flowering as it does freely before the varieties of *C. Trianae*. A truly grand plant of *C. dolosa Walkeriana* was at home upon a block and covered with its rich purple blooms. This dwarf-growing species is a gem, and where those possessing rich fragrance are desired this should be grown. *Cymbidium Lowianum atropurpureum* was just commencing to unfold twenty-one of its flowers on a large spike. The deliciously fragrant *C. eburneum* was also displaying its attractive ivory white flowers.

The wealth of *Dendrobiums* suspended from the roof in the *Cattleya* house at different heights added much to the gay appearance of the house. The first plant to be mentioned was that old inhabitant of our gardens, *D. nobile*; a large basketful covered with bloom was suspended in front of the door, and the effect was all that could be desired. This is a grand Orchid, and when well grown and flowered is still unsurpassed. To the right hung a fine dark form of *D. nobile*, much finer than the variety known as *D. n. pendulum*, having broader and more darkly coloured sepals and petals; while the lip, which is a feature in *D. pendulum*, are in these two forms very similar. Of *D. Ainsworthii roseum* two or three plants were in full bloom, and the same may be said of its delicate yet lovely white form. The sepals and petals of the latter were of the purest colour, while those of the former were particularly well shaded. Those who have seen both these forms and have had opportunities of comparing them with the variety known as *D. Leachianum* would not long dispute that the latter is distinct from both. A number of the useful and attractive *Dendrobium Jamesianum* were standing upon the stage in flower in association with the *Cattleyas*. *D. Pierardii latifolium* was conspicuous with its pendant growths 4 feet in length, and well flowered for fully 3 feet of that length. *D. luteolum* with its cream-coloured flowers, and *D. moniliforme* may also be mentioned as being in good condition. Of *D. crassinode*, variety *Barberianum*, several plants suspended in the house with stout profusely flowered pseudo-bulbs were very attractive. The white form album was equally as well bloomed as the type, and the specimen noted had several flowering pseudo-bulbs. *D. Wardianum* with growths varying in length from 18 inches to over 3 feet in full bloom, and others ready to expand, would, when all out, be a sight worth seeing. But the white variety of this delicate yet gorgeous *Dendrobium* had a peculiar charm, for I had never seen it in flower before. Mr. Gaskell's specimen is a grand one, having several pseudo-bulbs covered with flowers. In growth it exactly resembles the type, not the giant form that has been imported from Burmah and now so plentiful in this neighbourhood. There is a wonderful similarity between the above variety and that of *D. crassinode album*, the yellow of the lip being perhaps a little brighter colour in the former than the last named, while the former has two small dark spots in the throat. Both are charming varieties. It may here be mentioned for the good of those commencing the cultivation of *Dendrobiums* that Mr. Davies, Mr. Gaskell's successful grower, does not give to these plants much material for their roots. *D. crassinode* may be given as an example. Two small rafts are secured together, and between them the smallest portion of sphagnum moss, the plants being made secure at one end of the rafts. No plants could be doing better, and it is clearly evident that many give these plants too much moss and peat to root in.

The warmest house contained many fine plants of *Aerides*, *Vandas*,

Saccolabiums, and others, but I shall pass these to notice the Phalænopsis. These are arranged at the north end of the house, the wall being covered with Ferns, Fittonias, and other similar plants. Many of the plants are standing upon the stage, but elevated about a foot above the rim of large pots and blocks of wood, while the remainder are in baskets suspended at different levels. Many of the plants were in bloom, and the magnificence of the display should be seen to be fully realised. A variety with the growth of *P. amabilis* was particularly conspicuous, having in the flower the yellow of *P. grandiflora*. *P. amabilis* and *P. Schilleriana* were very fine, while two plants in full beauty of *P. Stuartiana* were really grand. *P. leucorrhoda* is, perhaps, the finest of all Phalænopsids, having flowers 3 inches or more across, which resemble in size and shape those of its parent, *P. amabilis*; they possess the beautiful colouring of its other parent, *P. Schilleriana*. These plants do not like being moved about, and to show their peculiarity in this respect it may be mentioned that those noted above were removed from an old house to the new one which they now occupy, but they did not take kindly to their new quarters; but by care and judicious treatment Mr. Davies has during the past year restored them to their former health and vigour, and they are now in the best possible condition.

Cypripediums are in good condition and well represented. A large plant of *C. barbatum*, over 4 feet in diameter, although not in flower, cannot be passed without notice. *C. caudatum* has eight or nine spikes visible, and when its peculiar long petals are developed this plant will be interesting. A large flower of *C. Lawrencianum giganteum* was just past its best, having been crossed with that distinct and beautiful variety, *C. Spicerianum*. A good plant of *C. barbatum biflorum* with its two flowers on one stem, as its name implies, was well flowered. *Cypripediums* *Argus*, *Hookerii*, *lævigatum*, *hirsutissimum*, and *villosum*, a large plant with many flowers, were also worthy of mention. In the cool house there was a good opportunity of comparing the varieties of *C. insigne*, *C. i. aureum* being good, but a form named *C. Chantinii* was very much superior, being both larger and finer than the flowers of *Maulei*, the plants of both being equally strong. In the warm house was a very fine plant of *Dendrochilum glumaceum* with twenty-five of its hangingspikes, which scented the whole house. This Orchid is worth growing more largely in gardens, as it is admirably adapted for cultivation in baskets, and has a very beautiful appearance when in flower suspended from the roof. *Leptotes bicolor* was also pretty.

In the houses devoted to cool Orchids quantities of *Cælogyne cristata*, large pans 3 feet or more in diameter, which had been masses of flower, were just over. The *Trentham* variety was still at its best, and is valuable because it flowers later. *C. Lemoniana* was in full beauty, and flowers much later than the ordinary variety of *C. cristata*. The plant of *C. Lemoniana* is over 3 feet over, and has the peculiar habit of flowering freely from the top of the pseudo-bulbs in autumn, and from their base the same as *C. cristata* at this season of the year. This is the character of the plant under Mr. Davies' charge, and it would be interesting to know if this is natural to this variety. Many plants of *Lycaste Skinnerii* of various shades were in full flower, while very fine plants of *Lælia anceps* were past their best; these must have been very fine. The *Odontoglossum* house was very gay with numbers of *O. Alexandræ*, *O. Pescatorei*, plants of *O. Hallii* with seven or eight large spikes, and many others. Several plants of *O. odoratum* were in flower, but one struck me as a remarkably fine distinct form, having a pure white lip with a purple spot upon it. *O. Rossii majus* and *O. Cervantesii* were attractive, suspended from the roof in shallow pans in association with the bright scarlet flowers of *Sophronis grandiflora*. The last is a great favourite, and Mr. Gaskell intends to have sufficient to fringe the whole of the house devoted to *Odontoglossums*; and what is easier of cultivation or more beautiful at this season of the year?

Although many new and rare species and varieties are to be seen at Woolton Wood, yet room is found for good useful old kinds. *Phajus grandifolius* is one of these, and I noted a large plant with over two dozen spikes, and it would be difficult to select an Orchid when in flower that is more noble or commanding. *Calanthes* a short time ago were a great feature of attraction, one large house being filled with them while in bloom. I need scarcely add that where these plants are grown in large numbers such a sight once seen seldom fades from the memory. These plants are held in such high estimation that it is proposed to construct a house for them. The plants of *C. veratrifolia* which are grown in the stove are wonderful examples of cultivation, and a competent authority considers them the finest plants in Europe. They are growing in 10-inch and 12-inch pots, and are the picture of health; in fact they resemble *Phajus grandifolius* in size and strength more than *Calanthe veratrifolia*. These plants are well elevated above the rim of the pots except one plant, which is not in good condition, but has been potted differently on someone's recommendation. These *Calanthes* are potted in about equal parts of fibrous loam and peat; with a very liberal quantity of sandstone intermixed, and a few quarter-inch bones with the meal left amongst them as crushed. Mr. Davies feeds these plants liberally, and can do so with safety when small pieces of sandstone are freely employed in the compost.

There is a house full of *Masdevallias* in the best of condition just commencing to throw up their showy flowers.—W. BARDNEY.

NARCISSUS "JAMES DICKSON."

In reply to your correspondent "Narcissophile" under the above heading in your valuable paper (May 1st), we did not send the flowers to the Floral Committee of the Royal Horticultural Society until after we had

purchased 1000 of the bulbs from Mr. Pickstone. The name as applied had previously been given to it by Mr. Burbidge at the Daffodil Conference on April 1st, and, curiously coincident, the same name was given by the Rev. C. Wolley Dod. We have purchased the entire stock of flowering bulbs of this grand variety from Mr. Pickstone, and it was by his special desire that we wrote to the Floral Committee to change the name to "Sir Watkin," which they declined to do. Our intention is to send it out under the name of "Sir Watkin" early in the approaching autumn.—JAMES DICKSON & SONS, *Newton Nurseries, Chester*.

NATIONAL AURICULA SOCIETY.

NORTHERN SECTION.

THIS Exhibition, which was held in the Manchester Town Hall on Tuesday the 29th ult., was, in the opinion of many, not quite equal to those of former years, last year in particular. Undoubtedly the chief reason is the backward condition of many collections. Several large growers were almost unrepresented, notably the Rev. F. D. Horner, Wm. Bolton and Richard Gorton, Esqs., and some others were not in such strong force as on some other previous occasions; nevertheless a good display was made, and it is worth while going a long way to witness the intense enthusiasm of the numerous growers, be they in humble or affluent circumstances. If a suggestion may be made here, it would be that the Committee should encourage the exhibition of larger collections, say fifty varieties, also to secure a larger number of Alpine exhibits, as that class is evidently very rapidly gaining the popular favour. Again, a much better and more distinct method of labelling should be insisted upon than exists at the present time. Growers know their plants as soon as they see them, but the public do not, and the greatest difficulty is experienced in getting at the proper names of the plants when pasted on the pots, and frequently most indistinctly written. These are matters well worthy the consideration of the Committee, and undoubtedly their efforts to develop improvements will be cordially appreciated by the public and flower-loving section of the Lancashire community. A very large number of people visited the Exhibition, and at times the building was uncomfortably full. The Auriculas were fittingly supplemented by a very attractive display of stove and greenhouse plants.

SHOW AURICULAS.—Six dissimilar varieties.—In this class there were seven collections staged, all of which were good. First Mr. H. Wilson, Halifax, with grand plants of *Prince of Greens* (Trail), nine pips: Col. Taylor (Leigh), Acme (Read), Lancashire Hero (Lancashire), John Simonite (Walker), and Mrs. Douglas (Simonite), all of which showed evidence of the best culture, the plant of John Simonite was especially praiseworthy. Mr. E. Pohlman, Halifax, followed with a very even collection as follows:—*Prince of Greens* (Trail), *Trail's Beauty*, *Brilliant* (seedling), Acme (Read), Col. Taylor (Leigh), and Alexander Meiklejohn (Kaye). The finest plants were *Prince of Greens* with eight charming pips, and *Trail's Beauty* with nine very large pips; the flowers of Acme were also good. Third Wm. Brockbank, Esq., Didsbury, whose best plants were *George Lightbody* (Headley) and Lancashire Hero (Lancashire), the latter being especially good. Fourth Mr. Ben. Simonite, Sheffield, whose collection included *Merlina* (Simonite), *Heather Bell* (Simonite), and a new seedling. Fifth, Wm. Bolton, Esq., Warrington; sixth, Mr. E. Shaw; seventh, Miss Stewart, York.

Four dissimilar varieties.—The premier position was again taken by Mr. H. Wilson with very neat plants, comprising *Garibaldi* (Pohlman), with seven first-rate pips; Col. Taylor (Leigh), Acme (Read), with six very even pips; and *George Lightbody* (Headley). A close second was gained by Mr. Pohlman with Acme (Read), *George Lightbody* (Headley), *Ellen Lancaster* (Pohlman), and Col. Taylor (Leigh); the plant of *Ellen Lancaster* was especially noteworthy. Mr. Wm. Taylor, florist, Middleton, was third; Wm. Brockbank, Esq., fourth; Wm. Bolton, Esq., Warrington, fifth; Arthur Potts, Esq., Hoole, Chester, sixth, this collection containing a good plant of *Dr. Horner* (Simonite); and Mr. E. Shaw, seventh. There were nine collections staged in this class, some of them running very close in merit.

Two dissimilar varieties.—As usual this was a very full class—sixteen pairs were staged, the honoured ones selected in the following order. First, Mr. E. Pohlman with *Read's Acme* and *George Lightbody* (Headley), the former with seven very excellent pips, and the latter with six extra-sized pips. Second, Mr. John Beswick, Middleton, with *George Lightbody* (Headley) and Chas. J. Perry (Turner), the latter with ten large pips. Third, Mr. Wm. Taylor; fourth, S. Barlow, Esq., Stakehill, Manchester; fifth, Mr. R. Lord, Todmorden; sixth, Mr. E. Shaw; seventh, Mr. H. Wilson. This formed a most interesting class.

Pair, for maiden growers.—Arthur Potts, Esq., took the lead in this class with *Booth's Freedom* and *Lancashire Hero* (Lancashire), the former with six fine pips and in excellent condition, and the latter with six pips. Mr. J. Brodie, Rochdale, was second. These were the only two exhibitors in this class.

SINGLE PLANTS.—*Green-edged*.—In this class, as well as every other for single specimens, the competition was very keen. A large number of plants being staged, great difficulty was experienced in selecting the best for the awards. The premier was a plant of *Lancashire Hero* (Lancashire), the owner's name being not given on the card; after this the first prize was taken by Mr. R. Lord for a seedling of very promising character. Mr. E. Pohlman was second with *Prince of Greens* (Trail), and a grand plant it was, with ten fine pips. The following awards were made respectively—third, Mr. Jno. Beswick; fourth, fifth, and eighth, Mr. Ben. Simonite; sixth, Wm. Brockbank, Esq.; seventh, Mr. E. Pohlman. There were thirty entries in this class.

Grey-edged.—The premier was another grand plant of *George Lightbody* (Headley) from Mr. H. Wilson, carrying seven good pips; after which the first prize was given to a good specimen of *Alexander Meiklejohn* (Kaye), the owner's name not transpiring. Mr. E. Pohlman was second with *Lancashire Hero* (Lancashire); third, Wm. Brockbank, Esq.; fourth, Mr. B. Simonite; fifth, Mr. J. Simonite; sixth and eighth, S. Barlow, Esq.; seventh

R. Heys, Esq., Rochdale. This was also a very keenly contested class; upwards of forty specimens were staged.

White-edged.—The premier was granted to Mr. H. Wilson for a fine plant of Acme (Read), bearing nine very large and even pips. First, Mr. R. Lord, with the same variety; second, fifth, and seventh, Mr. H. Wilson; third, fourth, and sixth, Mr. Ben. Simonite; eighth, Mr. R. Lord. The plant of Trail's Beauty, gaining the third prize, is especially worthy of mention, carrying eight very fine pips. There were upwards of thirty plants staged in this class.

Sels.—In this class there was very keen competition, as there were over fifty plants staged. Premier, Wm. Brockbank, Esq., with a seedling named Lord Rosebery, a ruby body colour, with a good tube. Mr. Jno. Beswick took the first prize with an excellent plant of Lord of Lorne (Campbell); second and fifth, Mr. E. Pohlman, with Brunette (Pohlman) and Ellen Lancaster (Pohlman); third and sixth, S. Barlow, Esq., with Ringleader (Barlow) and a seedling; fourth, Wm. Bolton, Esq.

ALPINE AURICULAS.—Four dissimilar varieties, shaded.—First, S. Barlow, Esq., with very handsome specimens of President (Turner), Mrs. Llewelyn (Turner), Unique (Turner), and Mrs. Dodwell (Turner). Mr. Jno. Beswick was a good second, all his plants being very fine, especially Diadem (Gorton), with sixteen pips; Dazzle (Turner) was also very fine. Third, Mr. E. Shaw; fourth, Mr. R. Heys; fifth, Wm. Brockbank, Esq.; sixth, Mr. Prescott.

Single plant, yellow centre.—Premier, Mr. E. Shaw, with Diadem (Gorton), carrying an enormous truss of bright flowers. Mr. R. Heys took the first prize with a good seedling; second, Wm. Brockbank, Esq., with Mariner (Turner), the same grower taking third; fourth and fifth, Mr. J. Geggie and Mr. E. Pohlman respectively. This was a very closely contested class, there being not less than thirty plants staged.

Single plant, white ground.—There were about twenty entries, but many of the plants were weak, and scarcely white grounds. Premier, Mr. E. Pohlman with a very handsome seedling, the same grower taking the first prize also with another seedling of great merit; second and third, Mr. R. Heys and Mr. Partington, Middleton, in the order named.

POLYANTHUSES.—Three dissimilar, black ground.—First, Wm. Brockbank, Esq., with Exile, bearing ten perfect pips, and rarely has it been shown so good; Beauty of England and Cheshire Favourite, the former with six and the latter with seven pips. The growth of these plants was remarkable, the strongest evidence that Polyanthus are happy at Didsbury. Second, Mr. John Beswick, with excellent plants, comprising Exile, Blackbird, and Lord Beaconsfield; third, S. Barlow, Esq.

Three dissimilar, red grounds.—In these Mr. John Beswick took the lead, although the second collection was very close in merit. His plants were Sidney Smith, Lancer, and George IV., the latter being the strongest plant; Lancer was very fine. Wm. Brockbank, Esq., was second with President, Prince Regent, and Lord Derby; the latter is a very fine variety. Third, Mr. R. Heys, with George IV. (again good), Formosa, and Prince Regent; fourth, S. Barlow, Esq.

Single plant, red ground.—There was not less than twelve entries in this class. Premier, Mr. R. Heys, with George IV.—a splendid plant, with seven large and perfectly formed flowers. First and fifth, Mr. Jno. Beswick, with Lancer and Minnie; the former again very fine. Second, S. Barlow, Esq., with a meritorious seedling; third (owner's name not given), a good plant of George IV.; fourth and sixth, Wm. Brockbank, Esq., with Prince Regent and Lord Derby.

Twelve dissimilar, fancy varieties.—Wm. Brockbank, Esq., was the only exhibitor in this class. The collection staged was very attractive, but a good deal of the hybrid Primrose breed existed in the flowers; indeed, some of them more Primrose than Polyanthus in our opinion; however, they well merited the award.

FANCY AURICULAS.—There was a class provided for twelve dissimilar varieties of these. S. Barlow, Esq., was first; W. Bolton, Esq., of Warrington, second with very pretty plants, showing a marked deviation from the typical florists' flowers.

PRIMROSES.—Twelve dissimilar.—Mr. Brockbank was the only exhibitor in this class, his collection including double and single varieties of ordinary merit.

MISCELLANEOUS EXHIBITS.—These as usual materially assisted to make the Show a success, although none of the collections staged were prompted by the prospect of money prizes. A group of Polyanthus Cheshire Favourite from Mr. Thomas Walker, nurseryman, Nearsden Road, Sale, showed how well that variety can be grown in the neighbourhood of Manchester; they were very healthy and vigorous. Varieties of Primula Sieboldi from Mr. G. Geggie of Bury, Lancashire, were also very attractive, and all were good. Mr. Geggie is making a speciality of these lovely flowers, and the issue is certain, if one may judge from the charming display here noted. Messrs. James Dickson & Son of Chester staged two stands of Auriculas, one of Show and the other Alpine varieties. The former were especially attractive, and conspicuous amongst them were plants of Lord of Lorne (Campbell) carrying three large trusses; C. J. Perry (Turner), one truss with twelve pips; Frank Simonite (Simonite), John Simonite (Walker), Acme (Read), Charles E. Brown (Headly), George Lightbody (Headly), Glory (Taylor), &c. The Alpines were also showy. The same firm also exhibited two stands of the now popular Japanese Maples; a first-class commendation was awarded for the exhibit. R. P. Gill, Esq., of Ashton-on-Mersey, also staged a batch of Japanese Maples, and a new seedling Atbyrium, raised by the gardener, Mr. Wm. Plant, which received a first-class certificate. The fronds are about 9 inches long, gracefully arching, with very small lateral pinnæ, the apex terminated with a broad tasselled head; it is a handsome sport.

Messrs. Fisher, Son, & Sibray of Handsworth staged a magnificent collection of stove and greenhouse plants. First-class certificates were awarded for Azalea Miss Beust and Vanda tricolor planilabris, and a certificate of commendation for a magnificent plant of Asparagus plumosus. Numerous Orchids and greenhouse Rhododendrons were conspicuous in this collection. In the former were Vanda tricolor amabilis, Trichopilia suavis—these were especially fine, Odontoglossums and Dendrobies. In the latter the brilliant scarlet Duchess of Connaught was conspicuous, the pink-flowered R. Taylori, the pure white Lady Alice Fitzwilliam, &c., the whole constituting a most effective and valuable group. A special feature of the Exhibition, too, was the grand mass of cut and pot Roses occupying the whole front of the

orchestra, exhibited by Mr. William Rumsey, Waltham Cross, for rarely have the Lancashire folk had such a feast of Roses so early in the season. The plants in pots were admirably grown, although not large, carrying excellent blooms, while the cut blooms were equally meritorious.

TEA ROSE NIPHETOS.

ALTHOUGH much has been said for and against this variety, I may be allowed to describe the culture from which we have derived the most success. It was planted three years since on the east side of a house devoted to Camellias with the roots outside, then only a plant with three small shoots. It made rapid growth, and being anxious for it to cover its allotted space we allowed it to grow unchecked, with the result that blooms were procured; although they were useful for house decoration were not in the strict sense of the word good blooms. In August, 1883, we determined to try a different process, which proved most satisfactory. It was pruned similarly to Vines, with the result that several shoots appeared on each spur, carrying blooms that were quite delightful. The syringe was freely used until the blooms began to expand, when its use was dispensed with, and aided by a temperature of 55° by fire heat kept the house free from damp, which is one of the greatest enemies this Rose has to contend with. I may add that after the first crop of blooms was cut it commenced growing and is carrying at the present time blooms well worthy its reputation. We use liberal dressings of horse droppings, which are renewed as they become exhausted. Care is taken to protect the stem outside during cold weather.—W. MAYBURY, *The Rookery Gardens, Dorking.*

[A finer example of this beautiful Rose we have never seen than the spray that was sent to us by Mr. Maybury, and which is represented in a reduced form in the annexed engraving.]

ORCHIDS AT WESTBROOK, SHEFFIELD.

I WAS greatly surprised at the tone of the letter of "F. F." on the above subject on page 344. I certainly had not any attention of writing "disparagingly" of "F. F." in my notes under the above heading of April 3rd, nor can I yet see that anything contained in those notes will bear that construction, as neither his name nor his work was mentioned. I cannot, however, allow such a curious letter to pass unnoticed.

I at once admit my error as to the date of the year when the sale of Orchids and subsequent death of the proprietor took place, and which he says was 1880, not 1881 as given by me. I can only repeat the statement in the editorial footnote, that this was an unintentional clerical error on my part.

He next says, "I had charge of them over three years." How is such a statement reconcilable with the fact that he entered upon his duties as gardener at Westbrook in September, 1880, and resigned those duties in February, 1883? Referring next to his correction of my statement as to the size of the two Odontoglossum houses. I did not give my figures as being the exact measurement of the houses, but only an approximation, and the figures given were qualified by the word "about." It does appear, however, that those figures were not far wrong, and the difference in size of the two houses is only some 3 feet in their length.

As to his statement concerning the Calanthes grown by him in 1882, I had the pleasure of seeing them when at their best, and gladly bear testimony to the fact that they were a splendid example of successful cultivation, and were, indeed, the finest of any I had ever seen, but at the same time I did not, I believe, see any spike 6 feet 6 inches long, though I well recollect "F. F." telling me he had them 5 feet 6 inches long. As to the 3 feet 2 inches length of bloom open at one time on one spike as stated by him, I did not see it. I at the same time saw the collection of Odontoglossums, and will only say that the condition of the plants was certainly far removed from what it now is.

Your correspondent says he will now allow readers of the Journal to judge for themselves. In this I concur, and I do not therefore intend to notice any further communication upon the subject.—W. K. W.

[It does not appear to us that any further discussion would be either profitable or interesting.—ED.]

NOMENCLATURE OF NARCISSI.

AT the Narcissus Congress of the Royal Horticultural Society, held on April 1st, 1884, the following resolution proposed by H. J. Elwes, Esq., and seconded by J. G. Baker, Esq., was adopted, and a Committee was appointed to revise the names now in use, in order to adapt them as far as possible thereto:—

Resolved—"That, in the opinion of this Conference, uniformity of nomenclature is most desirable, and that garden varieties of Narcissi, whether known hybrids or natural seedlings, should be named or numbered in the manner adopted by botanists."

The revising Committee met on the morning of the following day, when the names of the flowers then present underwent

Fig. 87.—ROSE NIPHETOS.

revision and correction in the sense of the resolution. Mr. Elwes presided. Mr. J. G. Baker kindly undertook to frame a table showing the botanical relationship between the several plants, while to Mr. T. Moore and Mr. P. Barr was deputed the further task of filling in the names of other garden forms and monstrosities. The list here printed is the result of their joint labours, the first portion showing Mr. Baker's grouping of the botanical forms, and the second portion the garden varieties arranged according to their botanical affinities.

THE CONGRESS CATALOGUE OF NARCISSI.

SERIES I.—GENUINE SPECIES AND THEIR VARIETIES.

[NOTE.—The names printed (large type) in the first left hand column represent the sub-genera, those in the second (italics) indicate the admitted species, those beneath them in ordinary type are sub-species, and the right hand column gives the varieties as understood botanically. The garden forms and monstrosities follow these.]

GARDEN VARIETIES OF SPECIES (SERIES I).

2. *Pseudo-Narcissus*—
albus, luteus, pallidus, Nelson, scoticus, serratus
sub-group: F. D. C. Godman, Nell Barry, Stansfield, variiformis, Wolley Dod
- 2a. nobilis of Redoute
- 2b. lobularis—
ampliorona
- 2c. major—
Beaconsfield, Backhouse's Queen, Captain Nelson, Corporal Trim, Cleopatra, Chinese Gordon, Eliza Turck, Evening Star, Greenback, Gertrude Jekyll, Gladstone, Golden Prince, Her Majesty, Hudibras, Havelock, John Nelson, J. G. Baker (volutus), John Vincent, John Bright, Joseph Chamberlain, Khedive, Little Princess, Lady Doneraile, Lord Mayor, Mr. Engelheart, Mrs. H. J. Elwes, Mrs. Gladstone, Mrs. Shirley Hibberd, Mrs. Nelson, maximus, M. J. Berkeley, Marie Louise, major luteus, major superbus, Morning Star (stellatus), Peri, propinquus, Prince George, President Arthur, President Lincoln, spurius, spurius coronatus, Sir Charles Dilke, Sir W. Harcourt, St. Bridgid, Shirley Hibberd, Sharman Crawford, Seraph, Thomas Moore (Mooreanus), Thomas Spanswick, Townshend Boscawen, Tottenham Yellow
- 2d. bicolor—
Alfred Parsons, Archbishop Haynault, breviflorus (bicolor, Bot. Mag.) Dean Herbert (primulinus), Duke of Edinburgh, Duchess of Edinburgh, Empress, George H. Barr, grandis (maximus), Horsfieldii, Harrison Weir, James Walker (albidus), J. B. M. Camm, Jeannette, Mrs. J. B. M. Camm, Mrs. Harrison Weir, Michael Foster (sulphurescens), Mrs. M. Foster, Murrell Dobell, President Garfield, Prince of Wales, Peabody, Sir R. Peel, T. S. Dorrien-Smith, William Robinson
- 2e. lorifolius—
A. F. Barron, anceps, Emperor, Edith Barber, J. W. H. Barr, Lady Dorothy, Mrs. W. Goldring, Lord Derby, P. R. Barr, rugilobus
- 2f. moschatus—
cernuus pulcher, Mr. Cowan (Cowani), Cecilia de Graaf, Dr. Hogg, Duchess of Connaught, Exquisite, F. W. Burbidge, G. F. Loder, Lady Grosvenor, Mr. Milner (Milner), Mrs. F. W. Burbidge, Marchioness of Lorne, pallidus præcox, Rebecca Syme, Sir Stafford Northcote, Sarah Tisdale, William Goldring (longipetalus)
5. *incomparabilis*—
concolor—
Autocrat (expansus), Bella (minor), Blucher, Chang, Edward Hart, Eclipse (grandiflorus), Hector, Jenny Lind, Provost, Sunray (stellatus), Sycorax, Wellington.
- Leedsii—
C. J. Backhouse, Figaro (expansus), Fairy (marginatus minor), Gloria Mundi, Glow (marginatus), Mrs. A. F. Barron, Sunlight (stellatus), Titan (grandiflorus).
- sulphureus—
Astræa (aureo-tinctus), Beauty, C. H. Dee, Darling (marginatus), Gil Blas (stellatus), Hogarth, John Bull (expansus), Johnny Sands, Magog (grandiflorus), J. F. Meston, J. T. D. Llewelyn, King of the Netherlands, Longshanks, Mrs. Meston, Nabob, Queen Sophia, Queen Mab (marginatus minor), Sir Christopher Wren.
- albidus—
Annie Baden, Adonis, Albert Victor, Bianca (expansus), Bride, Cupid (stellatus), Cynosure (albidus Leedsii), Fitzjames, Gog (grandiflorus), Jane Kolle, Lorenzo, Vesta.

pallidus—

Princess Mary of Cambridge, Prince Teck, semipartitus.

albus—

Consul Crawford, Charles Hooper, Claribel, Dove, Dr. Gorman, Duke of Buccleuch, Fair Helen (elongatus), formosus, G. F. Wilson, Harpur-Crewe, H. C. Smith, James Bateman, Marmion (aurantius), Montrose, Mrs. C. J. Backhouse, Mrs. G. F. Wilson, Poiteau, Queen Bess (albus magnificus), Roland (expansus), Rosa Bonheur, Stella, Surprise, William Bull.

giganteus—

James Dickson (Sir Watkin)

6. odorus—

Campernelli, trilobus, interjectus, rugulosus, minor (pseudo-juncifolius), heminalis.

8. Jonquilla—

major (large Jonquil), medius (lesser Jonquil), minor (least Jonquil).

9. Tazetta—

White with yellow cup: Bazelman major, Florence Nightingale, General Wyndham, gloriosus, Grand Monarque, Grand Primo Citronnier, Grootvoorst, Her Majesty, orientalis, Queen of the Netherlands, Sir Walter Scott, Staten General.

Yellow with yellow cup: Apollo, Bathurst, Jaune Supreme, Lord Canning, Sir Isaac Newton, Soleil d'Or, Sulphurine.

White with white or whitish cup: lacticolor, Louis le Grand, Luna, Paper White, precox.

12. poeticus—

March or April-flowering varieties—

ornatus, poetarum, radiiflorus (angustifolius), tripodalis. [It is no unusual thing for these to throw two or sometimes three flowers on a scape, but this peculiarity is not permanent.—P. B.]

April or May-flowering varieties—

poeticus verus, recurvus, patellaris.

GARDEN VARIETIES OF HYBRIDS (SERIES II).

1. *Humei*—nodding flowers with straight cup, nearly as long as dog-eared floppy perianth, tube variable in length; it connects the section Ajax with Queltia.

Hume's White, Hume's Sulphur, Hume's concolor, Hume's Giant.

2. *Backhousei*—bold habit; flowers horizontal with distinct basal tube, and long cup nearly equalling the spreading perianth; a connecting link with Ajax.

Cupid, Daisy, H. J. Elwes.

3. *Macleai*—sturdy habit, 1-2-flowered; flowers small, horizontal, with short tube, spreading perianth, and cylindrical cup.

major (Sabini), Parkinsoni.

3a. *Nelsoni*—1-flowered; flowers horizontal, with short tube below the broad spreading perianth, the cup cylindrical, rarely expanded at the mouth.

aurantius, expansus, Margaret Jones, major, minor, pulchellus.

3c. *tridymus*—near Nelsoni, but with somewhat more obconical tube, 1 to 3 usually 2-flowered; flowers varying much in size from that of Macleai upwards.

A. Rawson, Duke of Albany, Duchess of Albany, Grand Duke of Hesse, Innocence, Princess Alice, S. A. de Graaf.

4. *Leedsii*—flowers horizontal or drooping, with a long slender tube, spreading or dog-eared pallid perianth, and pale yellow cup varying from canary yellow to whitish, generally dying off white; differing from incomparabilis in the paler hue of its cup.

amabilis, Acis, Aglaia, Alexis, Albion, Ariadne, Arsinöe (gloriosus minor), Beatrice, Ceres, Circe (gloriosus), Cybele, Duchess of Westminster, elegans, Fanny Mason (Vincenti gloriosus), Favourite, Fides, Flora McDonald, Flora, Gem, grandis, Grand Duchess, Grand Duke, Hon. Mrs. Barton, Horner, Ianthe, Io (stellatus), Juno (galanthiflorus major), Katherine Spurrell, Leda, Madge Matthew, Mrs. Langtry, Mignonne, Maude, Minnie Hume, Maria M. de Graaf, Mrs. Barclay, Madame Patti, Oddity, Purity, Princess of Wales, Palmerston, Queen of England, superbus, Venus (galanthiflorus minor).

5. *Barrii*—usually dwarf and slender in habit; flowers horizontal, with long slender neck or tube, and spreading segments twice or more the length of the short expanded cup. (See *Burbidge's Narcissi*, t. 22, as illustrating the main features of the group.

Bullion, conspicuus, conspicuus minor, Lass o' Gowrie, Golden Mary, major, Model.

sulphureus—

Amy, Herbert von Bismarck, Milton, Prince Bismarck.

albidus—

Ada, Beatrice Murray, Cinderella, Eclipse, elegans, Gazelle, General Murray, Jewel, John Stevenson, Lucy, Mrs. Darwin, Mrs. Murray, Maurice Vilmoren, Miriam Barton, Piccio, Romeo, Sylvia, Vivian.

albus—

Betsy, Climax, Diana, Dirk de Graaf, Exquisite, Golden Star, Heroine, Jewess, Lilliput, Lady Gray, Sensation, Silver Star, William Ingram.

6. *poculiformis*—1-2-flowered; flowers nodding, white, with a long, slender, cylindrical tube, and a straight-sided cup, about half as long as the spreading, twisted, somewhat floppy perianth.

7. *gracilis*—rush-leaved, 1-3-flowered; flowers yellow, horizontal, with long slender tubes, spreading perianth, and shallow cup; late flowering.

8. *Burbidgei*—habit of poeticus; flowers horizontal, mostly white, with long slender tube, and usually with a shallow spreading cup, which is frequently stained on the rim more or less distinctly with orange red.

Arabella, Ariel (albidus), Alice Barr, Agnes Barr (delicatus), Amoret, Baroness Heath, Beatrice Heselstine, Boz (luteus), Blanche, conspicuus, Cowslip, Crown Prince, Crown Princess, Dandy (stellatus), Edith Bell, Ellen Barr, Empress Eugénie, elegans, Ethel, Golden Gem, gracilis, Guinever, Johanna, John Bain (grandiflorus), J. Golden Read, Jenny Deans, Joe, Little Dirk, Lottie Simmons, Little John, Mary (expansus), May, Marvel, Model, Ossian, Pearl, Primrose Star, Princess Louise, Robin

Hood, Sulphur Star, Thomas Moore, Absolon (grandiflorus expansus), Vanessa.

MONSTROSITIES.

2. *Pseudo-Narcissus*—

plenus, Telamonius plenus, lobularis plenus, lobularis grandiplenus, nanus plenus [said by Dr. Brown of Hull to have been raised by him from seed, one bulb only, and sent by him to the Conference; one bulb also received amongst bulbs of nanus from Lincolnshire by Mr. T. S. Ware, supposed to be the only double Narcissus raised since the time of Parkinson.—P. B.], cernuus plenus, cernuus bicinctus, capax plenus (eystettensis, Queen Anne's Double Sulphur Daffodil) [no person has yet satisfactorily determined which is the single form of this plant.—P. B.]

5. *incomparabilis*—

aurantius plenus (Butter and Eggs), albus plenus aurantius (Eggs and Bacon, Orange Phoenix), albus plenus sulphureus (Codlings and Cream, Sulphur Phoenix) [the supposed single form of this is semipartitus.—P. B.]

6. odorus—

minor plenus (Queen Anne's Double Jonquil).

8. Jonquilla—

plenus (Double Jonquil).

9. Tazetta—

romanus (Double Roman), nobilissimus.

12. poeticus—

plenus (Gardenia-flowered).

It should perhaps be explained in justice to the real workers in this field, that of the foregoing hybrids No. 1 Hume's hybrid, No. 5 Barr's hybrid, and No. 8 Burbidge's hybrid, bear names which are merely complimentary, the individuals thus complimented having had nothing whatever to do with the raising of the plants. The merit which attaches to the several productions belongs almost wholly to the late Mr. Leeds of Manchester and the late Mr. Backhouse of Weardale, and it is to the efforts of these gentlemen that we are indebted for so large and valuable an accession to the forms of these beautiful flowers which are now available for the decoration of our spring gardens. The exceptions are very few indeed, consisting mainly of the varieties named Gertrude Jekyll and Dr. Masters, which were raised by the late Rev. J. G. Nelson, and some three or four forms due to the labours of M. Max Leichtlin, of whom we may probably yet hear more in this connection, as we believe that gentleman is still earnestly occupied in the good work.—T. M.; P. B.

GRAPE HYACINTHS.

AMONG the early spring-flowering bulbs few, if any, surpass the beautiful and varied forms and colours of the Grape Hyacinth—Muscari. From a purely decorative point of view their suitability for either beds or borders can hardly be over-estimated, although it is only in the former of these two places that they can be seen to the greatest advantage, and for which purpose they are coming extensively into use both in private and public gardens, as well as for the supply of cut flowers in the market. They are also extremely useful for uncultivated places, under the shade of trees, &c., where they invariably hold their position, and even perceptibly increase, under the ordinary circumstances of Nature. Coming into flower as they do just as the Snowdrops and Crocuses are past, they make an agreeable and important succession to them, and, indeed, one we could ill dispense with at the present time.

They seem to thrive in any ordinary garden soil—that is, if it be not too stiff; and although some of them, such as M. Heldreichii and M. Szovitsianum, M. neglectum, &c., increase rapidly, they are easily kept within bounds, becoming as a matter of course more showy and interesting as the clumps increase in size and vigour. The best time I find to plant these is, as with nearly all hardy bulbs, the fall of the year, say from October onwards, well preparing the ground to a good depth with a liberal supply of old leaves before planting, and a depth of from 6 to 9 inches will be found best, as they are then not so easily disturbed by hoeing or cleaning the surface.

As the difference between the species is so small to the unpractised eye, the difficulty may be overcome by giving an extract of Mr. Baker's able summary of the species of Muscari in cultivation, and following it with a few notes on those most useful for cultivation in the garden.

GROUP I.—Perianth of fertile flowers obovoid globose, a little longer than broad; fertile flowers bright blue; leaves lorate, sub-erect.—M. botryoides, Mill., including M. Boraeum, alpestre festinum, and candidum; M. Lelierrei, Bor.; M. Heldreichii, Boiss., pulchellum, Jord. non Held.; M. Strangwaissii, Ten.; M. Aucheri, Baker; M. lingulatum.

GROUP II.—Perianth of fertile flowers obovoid oblong; about half as long again as broad; vernal; fertile flowers blue, broad-leaved.—M. paradoxum, Koch; M. grandifolium, Baker. Narrow-leaved.—M. pulchellum, Held.; M. Elwesii, Baker. Fertile flowers bright dark lilac, broad-leaved.—M. armeniacum, Baker; M. conicum, Baker. Narrow-leaved.—M. dilutum, Baker;

M. Szovitsianum, *Baker*; *M. micranthum*. Fertile flowers nearly white, teeth very little incurved.—*M. pallens*, *Fisch.* Autumnal.—*M. parviflorum*, *Desf.*

GROUP III.—Perianth of fertile flowers obovoid cylindrical, about twice as long as broad; leaves oblanceolate.—*M. latifolium*, *Kirk*; *M. Bourgai*, *Baker*. Leaves lorate; fertile flowers blue-black.—*M. commutatum*, *Guss*; *M. compactum*, *Baker*; *M. neglectum*, *Guss*; *M. pendulum*, *Trout*. Fertile flowers bright violet.—*M. concinnum*, *Baker*.—Leaves subterete; fertile flowers blue-black.—*M. racemosum*, *Mill*; *M. Morduanum*, *Held*. Fertile flowers greenish.—*M. maritimum*, *Desf.* Fertile flowers yellowish.—*M. Gussonei*, *Baker*.

Muscari botryoides, of which there are many useful garden forms and varieties, is one of the earliest to flower. The flower

Fig. 88.—*Muscari Szovitsianum*.

heads are nearly an inch long, light blue, and with globular flowers a little longer than broad; the leaves are nearly a foot in length at the time of flowering, glaucous, flat and broad, by which, apart from all other characters, it is easily distinguished from all the others. The varieties *album* and *pallidum* are both desirable plants, the latter especially, from the peculiar and rare shade of its blue.

M. Heldreichii, a variety of which is widely distributed in gardens under the name *pulchellum*, is a very fine free-flowering conical-headed plant, very showy, and having leaves of a beautiful glaucous green tint a little broader than the type. *M. Heldreichii* is nearly related to *M. botryoides*, but it has narrower and more erect leaves and much larger flower heads, increases rapidly, and is extremely useful in pots. *M. Aucheri* is also pretty, and deserves attention.

M. armeniacum is a very pretty and free-flowering species, and although pretty close in general appearance to *M. compactum*, it is easily distinguished from it in having dark lilac instead of blue-coloured flowers. The leaves are broad, nearly a foot long at the time of flowering, deeply channelled, and having an agreeable glaucous green tint. The flower heads are invariably about 2 inches in length, and the flowers, which are packed densely together, are of a dark or livid lilac colour

and having pretty white teeth. The uppermost, or sterile flowers, are bright blue. This species flowers late, often extending well into May, and when nearly all the others are past.

M. Szovitsianum is one of the prettiest and most profuse-flowering species yet introduced to cultivation. It has narrow roundish leaves, about 6 inches in length, much deeper channelled than in the above species, and but slightly glaucous. The flower heads are from 1 to 2 inches in length, flowers bright light blue or lilac, with white teeth slightly recurved. The upper flowers are sparse, much smaller and narrower than the lower ones, which never fail to mark this species. Its flowers, which are very fragrant, are abundantly produced in March and April, each bulb bearing several spikes. Very useful for pot culture. A native of the Caucasus and Persia, and stands our early spring frosts and east winds well. The woodcut, fig. 88, represents two spikes of this species. *M. micranthum*, a very fine and floriferous species, also belongs to this group, as also does *M. conicum*.

M. neglectum, having many flower heads, seldom less than between 2 or 3 inches in length, and having from thirty to forty flowers densely packed together, nearly twice as large as *M. Szovitsianum*, and very fragrant, black-blue, with incurved very pretty white teeth. The leaves are flat, strap-shaped, light green, very useful, and close to which comes *M. compactum* and *M. commutatum*. Found growing in the grassy meadows of Italy and Sicily.

M. racemosum.—This is one of the most easily increased of all the *Muscari*, belonging to the same section as the above, from which, however, it differs in having round instead of flat leaves. It produces yearly immense numbers of small bulbils, which increase rapidly in size, and often attain to the flowering stage the second year. The flowers are nearly black, very interesting, the heads being about 2 inches in length, upper flowers pale blue, contrasting agreeably with the lower.

M. Gussonei, a species with dull yellowish flowers, is still very scarce, but deserving of attention.—*M. S.*

SPORT'S PHYSIOLOGICALLY CONSIDERED.

(Continued from page 232.)

CELL-BUILDING is a process which is constantly going on in plant growth. Beyond the simple formation of cells, this union seems to be the means of the most important changes. To illustrate: The grains of pollen in a blossom are admitted to be independent male cells, which may be removed from one plant to another. In the same blossoms where the male cells are formed are the ovules or female cells, which cannot be removed without destroying them. These male and female cells are not independent parent cells—i.e., they cannot by division form other cells. Separately they can do nothing toward building up the tree, but soon perish. But bring the pollen or male cell in contact with the ovule or female cell, and they at once absorb the cell walls between them, unite their contents, and together form a new cell, which is the embryo or parent cell of a new plant. In this way every seed is formed by the union of the contents of two cells. And here we may see how no plant can, of itself, ever change its kind. If the pollen, or male cell, uniting with the female cell be of the same kind, then the embryo or seed cell must be the same, and the plant will be the same. But let the pollen or male cell be of a different variety, and although they will unite in the same way, yet the embryo or seed cell will be unlike either. It will be a mixed or hybrid cell, and the plant coming from it will be like it. Thus we see that all hybrids come from the union or mixing of the contents of two cells. The same is true of all cross-fertilised seeds. Two cells of different varieties unite to form a seed cell; hence the term "variety hybrid" applies to every crossed variety.

Now, we wish to examine this union of cells a little more closely. When two cells thus unite, each contains a nucleus which appears to be little more than a small collection of protoplasm. But what gives this little particle of protoplasm in the male cell the power to produce such different results when uniting with female cells of different varieties? Or, in other words, what determines the kind of the embryo cell thus formed? In a natural tree, isolated from all others, every seed or embryo will be true to its kind. But in a grafted tree bearing several kinds of fruit, perhaps no two seeds will produce the same kind. Now every nucleus or primordial cell is formed in the protoplasm, and it would seem that the protoplasm should determine the kind, but this is not the fact. Neither is it the root that affords the sap, nor the leaf that elaborates it, nor the protoplasm formed from it. I have a natural Pear tree, which, many years ago, was grafted with the St. Michael. When that Pear cracked so badly I grafted it with the Dunmore. Not satisfied with that fruit, I grafted it again with the Anjou. Thus, I have four kinds of Pear wood growing one above the other. The wild stock furnishes all the sap that passes up through the four kinds of wood, which is elaborated, digested, and assimilated by the Anjou leaves and branches, and forms protoplasm in the cambium of the Anjou top. It is certainly Anjou protoplasm, for it forms Anjou cells, buds, fruit, and wood. But this same Anjou protoplasm passes down a little lower and forms Dunmore cells, buds, fruit, and wood; still lower, it forms St. Michael cells, buds, fruit, and wood; lower still, the wild fruit of fifty years ago is found. And this all takes place when there are only Anjou leaves on the tree. Now, when the protoplasm leaves the Anjou top, it is full of primordial cells formed there, which, if matured there, would be Anjou. What changes their nature as they pass down? I come to the conclusion that each kind of wood must have an inherent power to determine its own kind of fruit, and that the nuclei or primordial cells have their kind determined by the wood where they are matured, and not where they originated. Every kind of wood imparts

something to every parent cell matured in it that determines what kind of fruit the tree coming from it shall bear. And every tree coming from such a cell must be true to its kind. If there is any way by which the contents of two cells, determined by different kinds of wood, should be united, would not the union be a hybrid? We have already seen that such a result follows in hybridising and cross-fertilising. We have also seen that in building up a tree the cells often absorb the cell walls between them, and unite their contents, and proceed to form new cells by their united contents. We are constantly bringing such cells in contact by the process of grafting, and it is in grafted trees that sports are generally, if not always, found. A cell in a scion is placed in contact with a cell in the stock; they absorb the cell walls between them, unite their contents, and these proceed to build a strain of wood different from either; in time this blossoms and bears fruit, uniting the qualities of both scion and stock. It is a graft hybrid, but is called a sport. I think all sports come from a union of cells of different varieties. We may not always trace this. As in the animal kingdom, the mixed strain may reach far back—sometimes over several generations—so in plants; the strain may not become apparent for years, but when it appears it gives a new variety.

There is another union of cells to which I wish to refer. A bud is virtually a single parent cell in its winter costume, with its spring ration enclosed. These bud cells may be split, and the halves of different ones united, thus mixing their contents as effectually as in hybridising. Mr. Meehan assures us that he has done it. During the last season I split the buds of several kinds of Apples and united them, and have three united buds living. I cannot tell what kind of fruit they will bear, but I know that halves of different buds united and grew well. This is a union of different cells, and I see no reason why their substance did not unite to form a parent cell which multiplied itself to build up the shoots just as any other cell does, and I cannot see why it will not be a mixed or hybrid wood, and bear a mixed or hybrid fruit. If so, I shall not call it a sport, but a graft hybrid. And such are all sports. They are hybrids resulting from the union of different cells. This certainly applies to the variegated Laburnum, Jessamine, and Abutilon, which we know were the result of grafting, and I think equally well to the Rose, the Apple, and all other sports. I come to this conclusion from the truths and principles found in the works of the most distinguished authors in our valuable library. Most of these authors speak of sports and graft hybrids, but none attempt to account for them except ex-President Clark of our own college, and he, rather doubtfully, in his report for 1870, says: "It may be possible that a part of a cell of the scion may unite with a part of the cell of the stock, and form a kind of mechanically crossed cell, capable of reproducing itself in infinite variety." This "infinite variety" is foggy. If he had said, capable of producing a new variety, it would have been nearer the truth. But if he had considered what he had already stated about the union of cells by the absorption of their transverse septa, he would have seen that it is not necessary to take parts of cells, but that by simply bringing cells of different varieties together, they will often absorb the intervening cell walls, unite their contents, and form a mixed cell producing a new variety, and all that is mechanical about it is the method by which the cells are brought in contact. From the foregoing I conclude that all vegetable sports are hybrids, produced by the natural union of cells of different varieties, and that when more familiar with the subject we shall no longer call them sports but hybrids.

ROCHDALE AURICULA SOCIETY.

THE second annual Show of this recently revived Society was held in the Public Hall on Saturday last. The display of Auriculas was very good, every class being well filled, and in nearly every case the competition was close. In addition to the Auriculas, collections of stove and greenhouse plants were staged for the decoration of the Hall by S. Barlow, Esq., Stakehill, and J. H. Lancashire, Esq., Deepdish Hill. Mr. Barlow also sent two large baskets of Primula Sieboldi varieties, and one of Primula rosea. Mrs. Scholfield, Fern Lea, sent a good plant of Dendrobium Wardianum, reflecting much credit on her gardener, Mr. Butterworth. Dr. Morris sent a fine plant of Trillium grandiflorum, having thirteen expanded flowers, and a seedling Trillium, which differs from the parent in having much larger flowers and larger and lighter-coloured foliage. This variety is very free-flowering, the plant in question having nineteen expanded blooms. He also staged a good specimen of Cypripedium pubescens. The Society is to be congratulated on the success of their Show. The Judges were Messrs. J. Booth, Failsworth; J. Cheetham, Rochdale; and T. Lancashire, Middleton, and their awards were as follows:—

Six dissimilar Auriculas.—First, Mr. H. Wilson, Halifax; second, Mr. Pohlman, Halifax; third, Mr. W. Bolton, Warrington, the same gentlemen occupying similar positions in the class for fours. The pair class was well filled, and Messrs. Pohlman; S. Barlow, Stakehill; and J. Beswick, Middleton, were the successful exhibitors. In a class for pairs from small growers the prizes were taken by Messrs. L. Heys, executors of J. Fletcher, and E. Elliott, all local growers. The maiden class pairs were allocated to—first, Mr. Brodie, Rochdale; second, A. Potts, Esq., Chester; and third, Mr. S. Lord, Rochdale.

ALPINE AURICULAS.—Four dissimilar varieties.—First, Mr. Beswick; second, Mr. R. Heys, Norden; third, Mr. Pohlman. Single plants.—Premium and first prize, Mr. Pohlman, with seedlings; second, Mr. Beswick, with Goliath of the Alps; third, fourth, and fifth, Mr. R. Heys, with Diadem and seedlings; sixth, Mr. Barlow, with a seedling.

Green edges.—First, Mr. Wilson, with Col. Taylor; second, Mr. Potts, with Prince of Greens; third and seventh, Mr. Pohlman; fourth, Mr. Beswick; fifth, Mr. Potts; and sixth, executors of J. Fletcher.

Grey edges.—First, Mr. Wilson, with Lancashire Hero; Mr. Pohlman taking first, third, fourth, and fifth; Mr. Royds second; and Mr. Bolton sixth prizes.

White edges.—Mr. Lord premium and third with Acme and Catherina; Mr. G. H. Wheeler, Rochdale, second with Trail's Beauty; Mr. H. Wilson second and fourth; Mr. Bolton fifth; and Mr. Pohlman sixth.

Sels.—Mr. Pohlman premium with Ellen Lancaster; Mr. S. Barlow was first, fourth, and sixth with seedlings; Mr. Royds was second with a seedling; Mr. R. Lord, Todmorden, third; and executors of Mr. J. Fletcher, fifth.

POLYANTHUSES.—Pairs.—First, Mr. J. Beswick, with Lancer and Exile; second, executors of J. Fletcher, with Cheshire Favourite and George IV.; third, Mr. R. Heys, with Cheshire Favourite and George IV.; fourth, Mr. S. Barlow, with a seedling and Prince Regent. In single plants Mr. Beswick took the premium, first, second, third, and sixth prizes; Mr. Barlow was fourth; and Mr. S. Lord fifth.—JAMES BRODIE, Hon. Sec.

KITCHEN GARDEN.

MAY is one of the most trying months for the kitchen gardener, as a constant watch has to be kept on young seedlings. Failures of seed will now be found. All kinds of grubs and insects are most likely to attack tender young crops, and, worst of all, the weather may not prove so genial as could be desired. Having to contend with these difficulties makes May anything but a comfortable month, and we can only advise perseverance, as in a few weeks everything will be growing strongly, and any extra attention devoted to the crops now will be amply compensated for by-and-by.

Snails and slugs are always plentiful and very active at this season. In the early morning and just before dark at night are their favourite feeding times. In wet weather they are sure to be busy then, but when the ground is hard and dry they are not troublesome. All young vegetables are liable to be eaten by them, and we strongly recommend a sharp supervision. Gathering them with the hands is a very good way of dealing with them. Two or three of our garden boys scour our kitchen garden every morning by six o'clock, and we never suffer much from these pests. Soot and lime in a dry dusty state are also excellent for destroying them, and they act as fertilisers as well. If small handfuls of bran are put down about 6 P.M. covered with a Cabbage or Rhubarb leaf, and looked at three hours afterwards, crowds of snails will be found congregated on the bran, and they can then be destroyed. This is the best of all traps for them.

Salsafy and Scorzoneria.—These are most useful winter vegetables, and to have them in perfection from November onwards the seed should be sown now. An open soil is most suitable for them; the drills should be 15 inches apart, 2 inches deep, and the seed should be sown very thinly, as ultimately the plants should stand 10 inches apart.

Celery.—The earliest may now be put out in the trenches. The plants should be lifted from their present quarters with good balls of soil attached to the roots, and as soon as they are planted in the trenches a thorough good watering should be given. Attention must be given to this at all times as the only means of preventing early Celery running to seed. Respecting the distance they should stand apart, we never like to have the plants closer to each other than 10 inches.

Runner Beans.—Do not sow all these at once or in May, but keep some and sow about the middle of June, when a fine lot of healthy tall bearing plants will be the result. It is a common mistake to sow this crop too early, and the consequence is that tender pods are generally very scarce in October and November, but they need not be so if this hint is borne in mind.

Cauliflowers.—Fill up any blanks which may occur in the plantations. Thin out plants from the seed beds, and dibble them in where they will have more room. Sow a pinch of seed of Veitch's Autumn Giant to produce plants for putting out after Potatoes are lifted in June, and these will produce a fine batch of late heads in November.

Cabbages.—These are now heading freely. In cutting them, if the stumps are left they will produce a fine lot of small sprouts in two or three months hence, but where this plan is not followed clear them off at once and fill up with other crops. We prefer to have successional batches of plants heading rather than keep on the old ones and sow frequently. If a quantity of Suttons' All Heart or Dickson's Redbraes is sown now a fine lot of young and tender heads will be produced in September and October, and they are very acceptable then. Earth up spring-planted Cabbages, and do not let weeds grow between any of them.

Potatoes.—In many gardens Broccoli quarters are only now being cleared, and if any of their owners are doubtful as to whether to plant Potatoes there, we would say, Plant by all means. Early and second earlies are the best to put in, but all varieties will do well if the situation is favourable. Earth up all the early ones which are now showing above the soil in quantities. Any which may have been frosted down will sprout up again, although the stems will never be so strong, and the crop will be lighter than it would have been had all gone on well.

Watering.—In sowing seed or planting in very dry soil it is an advantage to water thoroughly after these operations; and when any vegetable crop, such as Peas or Beans, Lettuces or Cauliflowers, show signs of suffering for want of water it is best to give them a supply, but nothing is gained by surface dribblings, and merely wetting the foliage or the surface of the soil is worse than nothing. Water thoroughly or not at all, and then it does not matter whether it is done in the morning, noon, or night.

FRUIT FORCING.

PEACHES AND NECTARINES.—Earliest House.—As the fruit approaches ripeness, more air with a gradual diminution in the supply of moisture with a gentle heat in the pipes will insure good flavour.

Exercise great care in the removal of the fruit from the trees, as the slightest pressure of the fingers disfigures the fruit; and do not allow them to remain on the trees until they are dead ripe, when it is past its best for eating, the fruit being best gathered when it parts readily from the trees and laid on a padded shelf in the fruit room for a day or two, whilst that intended for packing should be gathered a day or two in advance of ripening as compared with that for home use.

Succession Houses.—Proceed with the usual routine, keeping the trees in vigorous health by the timely application of water to the roots and foliage, and mulch the borders with short partially decayed manure. Attend to early ventilation, and close early so as to husband the sun heat, and with plenty of moisture the swelling will be considerably accelerated. Should red spider appear more forcible syringings should be resorted to, to dislodge it, and if these do not answer promptly apply an insecticide, whilst for mildew dust with flowers of sulphur. If aphides be present fumigate on two or three consecutive evenings moderately, being careful to have the foliage dry and to deliver the smoke cool. In the battle with insects it is important that the onslaught be made upon their first appearance and before they have obtained a hold on the trees, when the moderate use of insecticides would prevent their spreading and injuring the foliage and fruit. Allow a moderate extension of the growth whilst the fruit is stoning, and in no case encourage more shoots than will be necessary for tying-in to furnish the trees and to supply wood for future bearing.

Late Houses.—The fruit in these promises to be more than usually valuable from the scarcity of fruit on the open walls in autumn; hence where there is a demand for late fruit arrangements should be made for meeting the deficiency by retarding the late trees in houses and wall cases, which must be done in the earlier stages of growth, and this is in every way preferable to shading the house when the fruit begins to ripen. If taken in hand now the midseason varieties may be kept back so as to ripen in September; but to effect this it will be necessary to throw open all doors and ventilators when the weather is mild, and to keep the floors well damped with cold water. Mulch over the roots with short manure, keeping it constantly moist, and in the case of trees that do not need stimulating employ cocoa-nut fibre refuse. The borders should be freely watered through the growing season.

MELONS.—*In Pits and Frames.*—When the pits and frames have been cleared of early Potatoes, &c., they may be filled with plants that have been reared for the purpose. In most cases it will be advisable to turn over the leaves, adding a little fresh litter or leaves, so as to bring up the bed to the required distance from the glass, allowing a few inches for settling, which will entirely depend on the manner the bed is made, for with the leaves firmly trodden together at the time of placing them in the pit the subsidence will not be great, but when put in loosely it will be considerable. In the case of beds for frames merely turning over the materials and adding a little fresh to keep up the sides will generate a genial heat sufficient to give the plants a start. Level the surface and put in the centre of each light a couple of barrowloads of soil, rather strong loam being most suitable, and spread this out so that a flattened hillock is formed 10 inches in depth, and the surface of the bed covered with soil 2 inches thick, and when this has been in the frames a couple of days the plants may be put out. Place a plant in the centre of each hillock, the plants having been well watered a few hours previous, pressing the soil firmly about them in planting; and if the sun be bright shade for a few hours daily until the plants become established, when it must be discontinued. Although it is advisable to turn over the beds and add a little fresh material, it may be dispensed with when the soil in the pits is already sufficiently near the glass, treading the soil down firmly and raising it a little in the centre of each light, so that the water may drain away from the collar of the plant. Admit a little air at about eight o'clock when there is the prospect of a fine day, and this will prevent scorching, keeping it through the day at 80° to 85°, and close at 3 to 4 P.M. on fine days, or earlier, according to the weather. Sow seed for raising plants to put out in pits, frames, or houses that will soon be cleared of bedding plants, bottom heat in their case not being essential, as by keeping close, ventilating early in the day, and closing as soon as safe in the afternoon, satisfactory crops may be obtained and be useful, as outdoor fruits do not promise to be very plentiful.

Cucumbers.—Plants in houses will need syringing twice a day, and both ways, so that every part of the foliage may be thoroughly cleansed of red spider; but if this obtain a hold use an insecticide at a safe strength. For thrips fumigate carefully, the same means being employed to destroy aphides. Afford liberal and frequent applications of tepid liquid manure to plants in full bearing, and be careful not to overcrop. Reduce fire heat as much as practicable, and let the atmospheric moisture be correspondingly reduced. Attend to the plants not less than twice a week for stopping, thinning out old growths and training young in their place, so as to keep up a succession of bearing wood; but be careful not to overcrowd, removing bad leaves as they appear. Shade only to prevent flagging.

Plants in frames will need watering over the foliage on fine afternoons, but every second or third day will be ample, and on dull days must not be practised. Keep the growths stopped one joint beyond the fruit, and do not allow them to become overcrowded, but thin out both young and exhausted growths gradually, keeping up a steady succession of growth showing fruit, and so insure an unbroken succession. To secure straight fine looking fruit place them in glasses. If necessary, sow for succession, it being better to have an over rather than an under supply of fruit. Still continue night coverings and attend to the linings as necessary.

PLANT HOUSES.

Phajus grandifolius.—Plants that have rested may now be turned out

of their pots, and the whole of the old soil shaken from their roots and fresh supplied. This should be done annually, for they will grow more luxuriantly when subject to this treatment than if left undisturbed for two or three years. While in active growth this Phajus requires abundance of water, and the soil soon becomes sour, which they dislike about their roots. For purposes of decoration they are the best in 7-inch or 8-inch pots, or even smaller. The pots should be well drained, but the soil must not be elevated above the rim of their pots; on the contrary, when potting is finished sufficient space should be left for water. In potting the soil must be worked well and carefully amongst the roots, and pressed moderately firmly into the pots. After potting place them in a close moist temperature of about 65° at night, and they will soon start into growth. Particular attention is needed in watering at first, for they make several inches of growth before fresh roots are formed; and if over-watered before their roots are active they seldom grow well or strongly. It is much better to err on the side of dryness than to give too much; in fact, if the atmosphere is moist very little water will be needed. These plants should not be syringed until they are growing freely, or the foliage is liable to become spotted. When they are growing freely and rooting the old foliage may be removed. The compost most suitable is good fibry peat and loam in equal parts, about one-seventh of cow manure prepared by drying, and then passed through a fine sieve; a little charcoal, meal, and quarter-inch bones and sand.

Calanthes.—The earliest plants of these have commenced growing from the base of last year's pseudo-bulbs, and may now be potted without further delay. A number may be placed together in pots if specimen plants are required, or they can be grown singly, which is the best for decorative purposes, as the smaller the pots the easier they are hidden when in flower by Ferns and other plants. The compost, temperature, watering, and syringing advised for Phajus will suit these plants well. If the watering be left to the inexperienced place them singly into 3-inch pots, to be transferred into 5-inch and 6-inch when they are growing and rooting freely. Careful watering and withholding the syringe in the early stages of growth is the secret of success. Calanthes do well in small wire baskets suspended from the roof, and when well grown they have a charming appearance when in flower. In baskets they should be started in pots, placing three or four together, according to the size of the baskets, in the smallest pots in which they can be placed, and finally, when growing freely, into the baskets. To increase the stock retain and pot all the old pseudo-bulbs, for nearly the whole of *C. Veitchii* will make plants. The tops of strong pseudo-bulbs may also be taken off and potted for the same purpose, and if strong many of them will flower in the autumn and winter.

Cattleyas.—These may be kept a few degrees warmer, the house ranging at night from 60° to 65°, with a rise of 10° by day. As many of them have commenced growth and are rooting freely, air should be admitted daily when favourable, and more moisture may be maintained in the atmosphere than has been necessary up to the present time. More water should also be given to those that are rooting freely. Care must be taken that water does not lodge in the young growths, for they are liable to damp if the atmosphere of the house is kept close and confined. If air is freely admitted after the plants have been watered there will be no danger from this cause. Those in flower should be stood at the coolest and driest end of the house, as the flowers will last much longer that they will at the warmer and moister end. If the plants can be taken into another structure while in flower so much the better. A sharp look-out must be kept for scale and thrips, especially the latter, which will soon spread and do much mischief if not eradicated.

Dendrobiums.—Such species as *D. Farmerii*, *D. chrysotoxum*, *D. densiflorum*, *D. thyrsiflorum* and others of this style of growth that have flowered have commenced pushing their growths from the base, and are in the best condition for repotting if they need it. These should be examined, whether grown in pots or baskets; if the latter are decayed give a larger size. As much of the old decomposed soil about their roots as possible should be removed, and fresh peat fibre and one-third moss with lumps of charcoal intermixed supplied. If in pots and well rooted the pots should be broken, and the portions to which the roots cling should not be disturbed but placed into the new pots. The pots must be well drained and the plants raised well above the rim. The surface should not be mossed until the plants are growing and rooting freely. Charcoal in good-sized lumps should be used freely. Water carefully until the plants are rooting freely, when liberal quantities may be given. Plants of *D. Devonianum*, *D. Wardianum*, *D. nobile*, *D. chrysanthum*, *D. crassinode*, *D. crystallinum*, *D. primulinum*, and many others in active growth should be syringed twice daily and given abundance of water. Watch the first-mentioned, for it is very subject to red spider, and must be sponged with a weak solution of Fir tree oil if observed, or it will soon arrest the growth. Red spider will not give much trouble if the atmosphere is kept moist and the plants well syringed.

SPRING PROSPECTS FOR 1884.

WHEN the cold dreary days and long nights of winter are over and the warm breath of spring is felt bees begin to stir themselves, casting aside with unmistakeable vigour the inactivity which has

through a wise rule of Nature kept our little friends in the warm shelter of the hive when to venture forth would mean certain death to them. We have now, however, reached a season of great activity among bees, and usually the enthusiasm and energy visible about every healthy stock is communicated to their owner, and displays itself in the increased interest taken in the bee corner of the garden. Business men are generally from home during the warmer hours of the day when bee work is most brisk, so that the first, what bee-keepers term "Glorious bee day," is enjoyed often during a Sunday stroll in the garden on a warm April day when pollen abounds nearly everywhere, or at least everywhere in the country wherever a Dandelion has room to grow. And does it not seem as if a contest was being carried on between our best stocks to see which could gather most in a given time. The bees appear to work for dear life, tumbling over each other in their desperate anxiety to get rid of one load and start off for another. No apiarian worthy of the name can have escaped the contagion of a scene like this, however careless he may have been about his bees, and no matter how small the interest taken in them while winter lasted, there is no avoiding the rousing-up which an hour among a dozen hives gives at such a time.

Unfortunately there is a tendency on the part of the inexperienced bee-keeper to allow this waking-up to run away with his discretion, and he wants to be as busy as his bees. Now there is nothing more commendable than the desire to be actively at work, pushing everything judiciously forward at the proper time in every possible way. But we must caution our readers against allowing interference with bees at this time to take a wrong direction which may have a very contrary effect to that intended. For instance, when a stock is seen for the first time working very vigorously, an almost irresistible impulse urges its owner to open the hive and examine the brood combs, not because there is any necessity for such examination other than a desire to know what progress is being made. We need hardly say how unwise it is to disturb bees in spring oftener than is absolutely necessary. There is in the modern system of management quite disturbance enough when giving additional combs or uncapping food, &c., so that anything like opening up stocks to satisfy curiosity, precisely as if a gardener dug up his seeds regularly with the very laudable view of seeing how they are getting on. We are induced to make these observations because the beautiful weather in the early part of April would lead many to begin taking liberties by way of manipulating hives and examining their contents at times when they would have been best left alone. Had the favourable weather continued it would have given an opportunity of considerably hastening brood nests in all hives of sufficient strength, but as it did not last more than a week such operations have been delayed. A change occurred when the perennial east wind began to blow, as it nearly always does at the wrong time for invalids and bee-keepers, and nearly the whole of the latter part of April has been rather unfavourable to bee prospects. Work could only proceed fitfully and at uncertain intervals. Where all has been put into close and cosy a condition as possible, entrances carefully watched, and feeding slowly and regularly kept up, much progress has been made inside our hives, so that we find most of our stocks in very fair condition indeed considering all things.

The mortality of the past winter has been much below the average, for except in cases of absolute starvation very few stocks so far as we can learn have perished. There has been an immense show of bloom on fruit trees of all kinds, and whenever the leaden clouds which have so persistently excluded the sun's rays for a great portion of the month allowed the warmth to be felt, it has been very cheering to bee-keepers to note how plentifully both honey and pollen could be gathered. Judging from a careful examination of our own stocks, and taking things altogether, we think the prospects of bee culture are very promising for a really good season.—W. B. C., *Higher Bebington*.

BEEES AND FLOWERS.

A VALUABLE paper upon "The Methodic Habits of Insects when Visiting Flowers," recently published in the "Entomologist," contains sundry comments on and explanations of some tabulated results of observations, which had been previously published by the Linnæan Society. From this paper we glean a few facts which are of general interest to bee-keepers. It is the positive conclusion of the author, Mr. R. M. Christy, that although it is admitted that insects of various orders play an active part in the fertilisation of flowers (that is, by conveying pollen from place to place, as also by their movements within flowers, aiding the transference of pollen from the anthers to the stigma), fully half this work is done by bees. The hive bee proves itself the most valuable of all, from the methodic habit upon which it almost invariably works, the only exception being that an individual will now and then be rather erratic in early spring. As yet, however, it has not been ascertained whether the Ligurian bee or the lately imported Cyprian bee imitate the old tenant of our hives in this particular.

Giving further explanation, Mr. Christy remarks that the method of the hive bee is shown by its strictly confining itself, while in its circuits amongst flowers, to the species it has first selected, rejecting or passing by other species that in form and colour may have a near resemblance. In a very large number of instances he believes that a bee seeks out but one species when taking its daily flight, although possibly each day might have a variation, but he rather thinks that for a longer time than that bees limit themselves to two or three favourites, and follow these up till they go out of flower perhaps. But, on the other hand, the majority belonging to a hive do not act in concert; still, amongst bees generally, is noticeable a preference for flowers that are blue. Colour is not their guide on the whole, it would appear, and it is suggested that a fine sense of smell guides them in their choice or rejection.

Mr. Darwin in one of his valuable books indicated this reason for the method shown by insects when visiting flowers. He says: "They are thus enabled to work quicker, they have learnt how to stand in the best position on the flower, and how far, and in what direction to insert the proboscis or trunk. They act on the same principle as an artificer does who has to make half a dozen engines, and who saves time by making consecutively each wheel and part for all of them." There are exceptions, it seems, to the systematic mode of working, caused by some bees being unable to distinguish closely allied species, and the humble bee takes rank as being more stupid than the hive bee. Such genera as *Ranunculus*, *Trifolium*, and *Primula* prove a puzzle to some, hence the production of hybrids through bee agency.

Bees have, so it is stated, a good sight for short distances, but a poor sight for long distances. When upon a flower a bee will stretch out its proboscis to obtain the honey from another that is near enough to be reached, or even fly a few inches from flower to flower upon a plant. On starting again it mostly flies in an irregular, apparently purposeless manner, and will often pass without notice flowers of the kind it is in search of; also a bee will unintentionally visit the same flower twice, or even thrice.—J. R. S. C.

SYRIAN BEES v. BLACKS.

BRIEFLY, in reply to "Hallamshire," the quotations referred to are taken from Mr. Doolittle's last article on the subject, being a reiterated statement, and a reply to Mr. Burton, which has not been answered. As to the charge of untruthfulness, to myself it is of little consequence, as I write under initials, but to Mr. Doolittle the charge would be more serious, even if less transparently gratuitous. One point will suffice to assay its value. It will be remembered that "Hallamshire," to carry conviction that Syrians were superior to blacks, stated that £20 of profit had been obtained in one year from one stock of Syrians, "while blacks did not gather enough honey to winter on." To this I remarked that the £20 quoted could not be the one I knew of, as that was made in the year 1881, when all stocks did well (I had in remembrance Mr. Abbott's instance as mentioned in the *British Bee Journal*). It now appears from "Hallamshire's" letter that this was the identical instance in the year 1881. Mr. Abbott says, page 64 of *British Bee Journal*, 1881, "Small nuclei with only a handful of bees in them to hatch out queens, have filled and been extracted repeatedly, and swarms and casts too small to send out (i.e., to sell) have produced treble their value in honey." "Hallamshire" says black stocks "did not gather enough to winter on." Comment is needless.—K. B. K.

TRADE CATALOGUES RECEIVED.

Thos. S. Ware, Tottenham.—*Catalogue of Dahlias*.
Cranston's Nursery and Seed Company, King's Acre, near Hereford.—*Catalogue of Roses and Herbaceous Plants*.
J. Cheal & Sons, Crawley, Sussex.—*Catalogue of Spring Flowers*; also *Catalogue of Florists' Flowers*.
Stephen Brown, Weston-super-Mare.—*Catalogue of Bedding Plants*.
Hennequin, Denis et Cie., Angers (Main et Loire).—*Catalogue of Flower and Vegetable Seeds*.

* * All correspondence should be directed either to "THE EDITOR" or to "THE PUBLISHER." Letters addressed to Dr. Hogg or members of the staff often remain unopened unavoidably. We request that no one will write privately to any of our correspondents, as doing so subjects them to unjustifiable trouble and expense.

Correspondents should not mix up on the same sheet questions relating to Gardening and those on Bee subjects, and should never send more than two or three questions at once. All articles intended for insertion should be written on one side of the paper

only. We cannot reply to questions through the post, and we do not undertake to return rejected communications.

COMMUNICATIONS.—Owing to the great pressure on our columns, several letters and communications that arrived on Tuesday and Wednesday mornings cannot be inserted this week.

Summer-pinching Fruit Trees (F. J.).—The "correct thing" is to study the condition of the trees and act accordingly. If they are fairly vigorous you may pinch early, but if inclined to be weak it is better to defer the operation, as their extended growth will encourage root-action. You will not err by allowing them to grow a little longer, and then pinch to four or five leaves. By pinching to three all the back buds might start if the trees are vigorous, and thus you would defeat your object.

Shoulders on Vine Bunches (L. Bannerman).—If the sketch you have sent is accurate, or nearly so (and we have no reason for doubt on that matter since we have seen hundreds of bunches like it), by all means take off the top isolated shoulder at once, or it will spoil what without it will be a good-sized and handsomely formed bunch of Grapes.

Propagating Passiflora (G. W.).—Portions of young shoots just getting a little firm, but not by any means hard, made into cuttings 3 or 4 inches long, strike freely if inserted in sandy soil and covered with a bellglass in a warm house, but the soil must be kept moist and the cuttings shaded to prevent flagging. We scarcely understand the condition of the slip to which you refer, but from what we can gather from your letter you appear to be adopting the best method of striking it.

Fungus on Tacsonia (R. C. W.).—The fungus is not the cause of the injury to the stem of your plant, but a result of it. The exuding sap affords a suitable medium for the germination of the spores, and the fungus spreads, as in the example you have sent. If you do not check the escape of sap and heal the wound in the stem your plant may collapse. We advise you to mix some powdered charcoal and freshly slaked lime together and cover the wound thickly. If the powder gets moist apply more, and with a little perseverance we think you will succeed in your object.

Topping Melons (Reader).—You have evidently missed some words out of your letter accidentally, and thus rendered your question somewhat obscure. We gather, however, that you chiefly want to know if a growth resulting from the topping will do as a leader for producing laterals for bearing fruit. It will do very well if the plants are well grown. We have grown hundreds of fruit during a series of years on plants similarly treated. If you desire to know more than this please state your wants as clearly as possible.

Apricots Eaten (W. S.).—We suspect that some of the fruits have been injured by frost, and have fallen off in consequence, while others may have been imperfectly fertilised, and therefore have not swelled. The fruits on the spray sent appear to have been eaten by large snails about the time of setting, and as the fruits swelled the injury would become more apparent. The tree is infested with leaf-rolling maggots, and unless these are picked off they will do much injury.

Setting Melons (Uxbridge).—You had better fertilise the flowers as they expand, about the middle of the forenoon when the pollen is dry being a favourable time for the work, and then when you have a sufficient number of fruits swelling regularly you can remove the surplus, and by that time few other flowers will be produced. The precise number of fruits to leave depends on the size and condition of the plants. Possibly the comparative failure last year was due, to some extent at least, to too much moisture in the frame and too little heat. This is often the case with frames heated with manure unless great care is exercised in adding fresh linings and using coverings for the glass judiciously.

Pelargoniums Luxuriant (San Juan).—It is not often that Zonal Pelargoniums produce such luxuriantly abnormal trusses, and we can only attribute the result in your case to an excess of nitrogenous matter in the soil, the result of the decaying turf and the added manure. An admixture of lime rubbish and very firm potting would have prevented the evil, which, however, we do not think will recur with these plants, though young and vigorous examples, unless potted as indicated, may be similarly disappointing. The spot is a disease apparently not more easy to account for than many little ailments which affect individuals. If the disease spreads the only remedy is to cut down the plants quite below the parts affected.

Mildew on Roscs (Idem).—In all probability the plants need more nourishment at the roots. Until the turf decayed they grew freely, but since then they have not had the support that was necessary for keeping them healthy. Give liquid manure copiously, with fresh soil if needed. Sulphur the pipes, also syringe the plants with a mixture of softsoap and sulphur. Mr. Bardney, who grows hundreds of Roses under glass, never has any mildew on them, but prevents its appearance. He boils 4 lbs. of softsoap for twenty minutes, then adds four gallons of water, and half a pint of this is added to four gallons of water and used every time syringing is done, whether once or twice a day.

Millipedes and Peas (J. A.).—The small worms you have sent are of a species of *Julus*, commonly known as millipedes, which appear to be unusually numerous this year, possibly in consequence of the extremely mild winter. We can suggest no safer mode of eradicating them than periodical applications of clear lime water. Try the effects of it and favour us with the results. You might also try petroleum experimentally, commencing with an ounce of the oil well incorporated in a gallon of water by violent and constant agitation during its application. The spray you have sent is of *Euonymus radicans*, which is grown for the beauty of its foliage, and you will possibly have to wait some time before the shrub flowers.

Abnormal Vine Leaves (J. G. & Co.).—We attribute the distorted condition of the leaves you have sent to a sharp current of air when the Vines were starting, which checked the expansion of the foliage, in fact injured the cuticle. When the force of the sap became greater the parts that were not injured developed with the curious result of which you have sent examples. We suspect also by the appearance of the large uninjured leaf that a rather high temperature has been maintained, and this would

render the effect of a driving current of cold air the more injurious. We have seen a similar example of distorted foliage on a Vine that was undoubtedly caused by the frost wind driving through the aperture over the top of a door, and when this was prevented the Vine produced no more abnormal leaves.

Mushroom Bed Failing (J. S.).—It is no trouble to us to answer the questions of our regular subscribers. In all probability the surface of the bed has been kept too warm, and perhaps been too thickly covered, hence the spawn has been attracted upwards, and has not taken possession of the bulk of manure. The temperature you name (65°) is about 10° too high for producing large fleshy Mushrooms. There are no finer Mushrooms produced than when a good portion of straw is included in the manure, but it must be well prepared. If you have not read Wright's "Mushrooms for the Million" the sooner you obtain it the better. It can be had post free from this office in return for 1s. 2d. in stamps. You can send stamps for your quarterly or half-yearly subscription to the Journal if you like, since you find it so difficult to get a post-office order. It appears you have not seen the paper since we answered your last question.

Amaryllis formosissima (Trike).—You are fortunate if all the imported bulbs you obtain produce flowers, as failures are not by any means uncommon. After flowering the plants must have a very light position in a moderately warm house or frame, and be induced to develop stout healthy foliage. In a very hot sunny position in summer the growth will become matured, this being essential for the production of future flowers. With active roots the plants must be freely watered until the leaves are fully developed, when the supply should be gradually reduced, and towards the autumn it may be withheld altogether.

Training Cucumbers (Idem).—You have done right so far provided the leaders are a foot apart. If they do not produce fruit-bearing laterals naturally, as they ought to do when half way up the trellis, the leaders may be topped again; the laterals that will follow should then be pinched either at the fruit or a leaf beyond it, according as space suggests, the pinching to be done as soon as the incipient fruit is seen, and one of the growths can be retained as a leader.

Marechal Niel Rose and Heliotrope (Idem).—We should shorten the shoots that have bloomed to such strong buds that you find show signs of starting freely, top-dress the roots if needed by removing a portion of the old soil and adding fresh, grow the plant in a very light house, keeping the foliage scrupulously clean, and thus induce young growths that would ripen and produce flowers another year. This Rose flowers much more freely on the young shoots made after this period than on the older wood that is shortened to spurs. Any variety of free-growing Heliotrope will do for the back wall, but we should grow it to a good size in a pot before planting in the border, and especially if the position be shaded.

Strawberries not Swelling (R. S.).—Assuming the plants have received no check at the roots, either by being allowed to get too dry at some time or by an overdose of liquid manure, we can only account for the hard state of the fruit to the sudden appearance of the sun acting powerfully on them after several days of dull weather. In the hot summer of 1868 we had quantities of Strawberries out of doors similar to those you have sent, and the only good fruits of President were obtained from under the leaves. If the roots of your plants are perfectly healthy we suspect we have indicated the cause of the evil, and we regret its occurrence on such a large scale, as it must be highly disappointing.

Mushroom Bed not Heating (Invicta, York).—The drenching that the manure received and then making into a bed so small is quite sufficient to account for the failure. Even the best of materials would scarcely ferment in cold weather in such small bulk. Even a trial bed should be at least 3 yards long. Small quantities of manure should be prepared under cover, such as in a shed or under a temporary arch of boards, zinc, or thatched hurdles. No particular time can be named for inserting the spawn. The only safe course to pursue is to wait until the bed has heated to its maximum and the temperature has commenced declining; then when it is about 80°, or perceptibly warm 2 inches below the surface, the spawn may be inserted. If a very thick covering of straw does not incite fermentation in your bed the only means to adopt is to get some fresh manure, making this the foundation, and covering it at least a foot thick with your present sweetened but cold material. The bed, however, is not large enough. The prices alluded to are retail.

Liquid Manure for Pansies (F. J.).—The diluted drainings from manure heaps are good for Pansies. Half a peck of cow or sheep manure placed in a cask containing from 20 to 30 gallons of water would also give you an excellent stimulant for the plants. Soot water made as has been so often described is also safe and good. This and all liquid manure should be used in a clear state, which may be effected by placing a few lumps of lime in the vessel, and afterwards removing the scum from the surface of the water. We have not had any complaints relative to the advertiser you mention, and we have therefore no reason to doubt his respectability. We will forward your letter to him if you desire us to do so.

Heating from Kitchen Boiler (J. Baron).—The water would not circulate in pipes 4 feet below the top of the boiler unless first forced into a water box at least 4 feet above it, and from this conducted round the conservatory. Then the boiler would have to be closed—not have a lid, as so many kitchen boilers have, and a feed cistern would have to be placed over the pipes in their highest point, and consequently the furthest from the boiler, level with the water box above alluded to. The water would then circulate, but not perhaps very briskly, whereas if pipes were simply taken from the boiler and made to dip down to the house below it would not circulate at all.

Lawn Sprinkler (An Old Subscriber).—We do not know the particular "sprinkler" to which you refer. If it is the same as an irrigator that has been exhibited in the Royal Horticultural Society's gardens by Mr. J. Deverill of Slough, it is useful for the purpose of watering lawns. It consists of pipes of various lengths elevated on a wheel carriage and furnished with jet and spray roses. It is readily moved about, and lawns are speedily and well watered where a good supply of water can be turned on for the purpose. It was awarded a certificate of merit in 1883. Endeavours shall be made to obtain the information you need on cotton culture.

Double Daisies (S. J. W.).—If all the twelve varieties have turned out to be "rubbish" we are strongly of opinion that the fault is in the soil or in the treatment to which the plants have been subjected. The best of varieties are very unsatisfactory in poor soil, or if they have been removed at the wrong time and not become established. Florists attach fanciful names to Daisies. There is a very fine white variety known as Victoria, The Bride, and Giant White; there is also a large deep red quilled variety known under the name of Rob Roy and Giant Red; also a mottled red-and-white variety that is very good. Those are the most effective we know, and are very fine when produced in the best condition; but grown under unfavourable circumstances they are inferior, and may be characterised as "rubbish." *Stipa elegantissima* is similar to *S. pennata*, and requires the same treatment. It is hardy, but not more beautiful than *S. pennata*.

Soil for Chrysanthemums (W. J.).—You write so intelligently, and appear to have such a thorough grasp of your subject, and as a consequence recognise the importance of proceeding cautiously, that we have no fear you will make any serious mistake in the soil you decide to use. As to the prepared composts, everything depends on the quantity of urine that was used in the soil; still, as it was safe for Cucumbers, and is likely to answer for Fuchsias, it will be safe for Chrysanthemums. The question is whether the lightness of the loam will unduly impair its lasting qualities. We fear this would be so, and though the plants may grow well for a time, their strength will not be sustained. We should consider the advisability of drying some clay and pounding it for adding to the compost. You will be the best judge on this matter, also of the quantity to use, as we cannot with sufficient exactitude comprehend the nature of loam that we have not seen. We think, too, a little lime rubbish and wood ashes would be an advantage, as we suspect that nitrogenous matter unduly preponderates in the compost, and might produce succulent growth. You can pot the firmer by such additions without impairing the porosity of the soil, and firm potting with light loam is desirable. If you can burn, or rather scorch some clay or heavy soil, then crush it, this would undoubtedly be good for mixing with the light and rich compost. Our reply is in the form of suggestions, and we can safely leave you to make the best use of them under the circumstances.

Vines not Thriving (G. McG.).—It is seldom that young Vines grow freely when planted in old Vine borders, unless stations of fresh soil are prepared for them, and they are then really in new miniature borders formed in the old. The failure, of which we have seen many instances, is more decisive if a considerable length of young cane is left when planting, as frequently must be the case for it to reach within the house or the wires, and severely shortening such newly planted Vines in the autumn previous to their insertion is always an advantage. When the roots do not readily take possession of the soil, and they certainly will not enter the old soil of a Vine border freely, the sap is extracted from the canes by the numerous buds more quickly than it is supplied by the roots. The growth is then stunted, premature ripening takes place, and not infrequently a species of fungus attacks the foliage, as in the example before us. The rusted or warted appearance of the leaves is, however, mainly due to excessive transpiration and the consequent shrinking of the tissue owing to the relatively weaker root-power and a deficiency of sap to compensate for moisture that has been lost. Sulphur will destroy the fungus, but that, we fear, will not be sufficient to induce the Vine to grow freely. In such paralysed Vines a healthy lateral not infrequently issues from the lower part of the rod, and when this is so it is a good plan to cut the Vine down to that portion, and healthy growth may follow. If the growth has several expanded leaves the rod may be cut down now and little bleeding will follow, as the healthy lateral will take the sap and grow more strongly in consequence. Under any circumstances such stubborn Vines may be cut down in the hope of a free-growing cane issuing from the base, but if cut below the leaves the operation must be deferred till the autumn.

Names of Plants (E. M. C., Limerick).—All plants that have been received at this office have been attended, but we do not remember any specimens with your name attached. (E. Moore).—The Daffodil is the double yellow variety of *Narcissus incomparabilis*, known as Butter and Eggs. (J. F.).—2, *Saxifraga oppositifolia*; 4, *Trollius europæus*; 6, *Caltha palustris flore-pleno* (double Marsh Marigold); 7, *Ranunculus aconitifolius flore-pleno* (Fair Maid of France); 8, *Ajuga reptans*. The other specimens were insufficient for recognition. (W. S.).—1, *Davallia divaricata*; 2, *Asplenium flabellifolium*. (D. H.).—Specimen much withered, but apparently it is *Scilla bifolia alba*. (L. C. H. R.).—A very poor specimen, resembling *Dondia Epipactis*.

COVENT GARDEN MARKET.—MAY 7TH.

THE SHROPSHIRE BREED OF SHEEP.

WE have always felt great interest in this breed of sheep, and it is with great pleasure that we enter upon the consideration of their origin and progress. Although these were originally a horned race, yet they were black in the face, which circumstance has greatly facilitated the introduction to our notice and for the use of the home farmer of a type of stock with a great similarity to the South Downs in the hands of some breeders; in others, however, they much resemble the Hampshire Downs.

As the origin of this breed was for many years a disputed question we are bound to allude to it. Some writers who assert that the original Shropshire Down sheep were a pure original breed, and this is no doubt correct, but it must be remembered that they were a horned breed with black faces; whilst other authorities, acknowledging their excellent style and character, they cannot allow them to be a pure breed. Our opinion is they are not a pure breed but cross-breed, and our information goes to show that they were obtained from the original Longmynd or old Shropshire sheep. Plymley in his "General View of the Agriculture of Shropshire," published in 1803, says, "There is a breed on the Longmynd with horns and black faces that seems an indigenous sort. They are nimble, hardy, and weigh near 10 lbs. per quarter when fatted. Their fleeces upon an average may weigh 2½ lbs. The farmers of the hill country seem to think the greatest advantage they derive from the access of foreign stock is from the cross of the South Down with the Longmynd sheep. The produce they state to be as hardy and to bite as close as the Longmynd sheep, and the weight of the carcase is increased." This seems good evidence as to the original characteristics of the old Shropshire stock, and it is also undoubted evidence that between sixty and seventy years ago this cross with the South Down and the Longmynd was a favourite. That this practice was continued for a considerable number of years cannot be doubted, for it was well known that first-class flocks of pure South Downs were kept in Corve Dale, and annual ram sales were held for many years until they were gradually superseded by the improved Shropshire Down, as many first-class breeders of Shropshire Down sheep resided at Corve Dale.

We have quoted evidence relating to the breed of sheep in the district of Corve Dale, yet we have important information relating to the breed from different parties in the district of Morfe Common. At a meeting of a farmers' club held in the county Mr. T. Meire some years ago observed, "It is not attempted to deny that the Shropshire is a cross-bred sheep. The original breed was horned, and the first attempt at improvement was to get rid of these incumbrances, and there is no doubt that this was effected by a cross of the Southdown." Again, Professor Wilson's report of the breeds of sheep in the Journal of the Royal Agricultural Society, vol. xvi., states, "On Morfe Common near Bridgnorth, which contains about 600,000 acres, there are about 10,000 sheep kept during the summer months, which produce wool of a superior quality. They are considered a native breed—are black-faced or brown, or a spotted-faced horned sheep, little subject either to rot or scab—weighing, the wethers from 9 to 11 lbs. per quarter after being fed with Clover and Turnips, and clipping nearly 2 lbs. per fleece, exclusive of the inferior portions, which may be taken at one-seventh of the whole."

Probably each of these districts in reference to which we have quoted contributed largely to the original stock as the agriculture of the county advanced, and the breeds became more valuable for their mutton as well as for their wool. It is well known the Morfe Common sheep were crossed with other breeds than the South Down, but more particularly with the long-woolled Leicesters and Cotswolds. The admixture of such different blood produced a corresponding variation in the character at that time of the breed of Shropshire Downs, and had tended very much to sustain the hesitation which existed until 1859 to allow them a place or class as a distinct breed at the meetings of the Royal Agricultural Society of England previous to the meeting held at Warwick in that year.

Few have enjoyed better opportunities of estimating the quality and characteristics of this breed of sheep than ourselves, by having performed the office as one of the three Judges of short-woolled sheep appointed at four separate meetings of the Royal Agricultural Society of England—viz., at Salisbury in

1857, at Chester in 1858, at Warwick in 1859, and again at the Great International meeting in Battersea Park, London, in 1862. Being thus engaged, it gave us an opportunity of noticing the character, not only of the Shropshires, but their comparative qualities with other sheep; for at the meetings at Salisbury and Chester a large number of different breeds of sheep were classed together in the competition, on which occasions the Hampshire Downs carried everything before them, for the new style and type raised by Mr. Humphrys of Oak Ash, Chaddleworth, Berks, were the wonder and admiration of all practical judges. In the succeeding year, however, at Warwick, when the Shropshires had a class to themselves, a great effort was made by their breeders and patrons. In confirmation of the rising popularity of this breed we may mention that they were supported by influential breeders at a distance—viz., in Staffordshire by Messrs. Masfen, Coxon, Hon. R. Curson, and Major Dyott; in Gloucestershire by E. Holland, Esq., M.P.; in Worcestershire by W. O. Foster, Esq., M.P.; in Warwickshire by Mr. T. Horley and Mrs. Baker; in Leicestershire by Mr. Pilgrim; and by Col. Pennant in North Wales. On reference to the entries at Gloucester (their first great start), Chester, and Warwick, we find them steadily progressing in number exhibited. At Gloucester the numbered 121, at Chester 184, at Warwick 192. In support of these remarks we now refer to the numerous entries for the local prizes offered for this class of sheep. The shearling rams numbered forty-three specimens, aged rams twenty-two, and twelve pens of five each of shearling ewes. The Judges especially noticed seven of the shearling rams, and generally recommended the aged ram and shearling ewe classes.

Previous to their being recognised as an established breed they were frequently noticed favourably by the Judges, although they were exhibited in the short-woolled class where all the best varieties were included. But at the Salisbury meeting the Hampshire made a great show, and also at Chester: the Oxfords, too, attracted attention. Nothing, however, brings out in full and perfect view animals when contending with each other being each of the same breed of a settled and established type; in fact it is a very difficult task for any judges to undertake to award prizes in classes where the numbers are great, for we have had as many as seventy-two shearling rams, including all the various types of short-woolled sheep, in competition in one class. Judges of great experience may sometimes lean to their better knowledge of certain breeds, or also to their peculiar and individual preference for particular types and style of stock.

(To be continued.)

WORK ON THE HOME FARM.

Horse Labour.—The seeding and preparation for Lent corn having been now finished, the preparation for root crops, commencing with Mangolds, should now be forwarded as much as possible, not losing a day after the land is ready for drilling the seed. This, however, if the weather continues dry, may be anticipated by soaking the seed in water for two days immediately before drilling. It is now too late and too much loss of time to apply yard or town manure and ploughing it under, but to save time we prefer to anticipate and arrange for the application of artificial manures some good ammoniacal manure, such as guano, about 3 cwt., or 3 cwt. of bone superphosphate per acre, will be enough to use by drilling with the seed. If the land is not equal to producing a full bulk and weight per acre of bulbs nitrate of soda may be applied by hand just before the first and second horse-hoeings or hand-hoeings. About 1½ cwt. at each horse-hoeing will push the growth forward very fast, and generally prove equal to a heavy weight per acre of bulbs. Still, however, bear in mind that if we should happen to apply more manure than the Mangold crop requires, that the residue will be a good investment towards the production of a Wheat or Lent corn crop which may follow. Carrots often answer very well as a mixed crop with early Swedes. The seed after being rubbed free of the burr or husk will drill readily in mixture with Swede seed, and recommend this mixed culture because Carrot plants in their second leaf when grown alone are so small that they are easily overpowered and destroyed by the weeds. When drilled with the Swedes the last week in May or first week in June the young plants may be left without thinning when the Swedes are hand-hoed the first time, while at the second hand-hoeing the Carrot plants may be set out or hand-pulled to distance without being so liable to be destroyed by the brown grub. In case of the Carrots being sown alone it should be upon stretches 16 inches apart, and we have found the garden hand-drill answer well for the purpose; but when the horse-hoeing has been done then hand-hoe the young plants to free them from weeds in the lines, but on no account to set them out at proper distance for a crop. Allow them to grow thickly in the rows until the Carrots for the most part are about the size of a man's finger; they may then be hand-pulled for sale or use in feeding horses or cattle, leaving just enough for a crop, so that when in full size the bulbs may nearly touch each other. We are now alluding to the short red intermediate variety of Carrot, for these are good for lambs or any sheep stock, and will also sell readily in towns for vegetable consumption, and also for horse-feeding. Many gentlemen set great value upon them as food for their carriage horses in the winter months, and they are certainly far better than any other roots for that purpose.

When the roots are hand-pulled in or about the beginning of August for thinning we have frequently obtained 14 tons per acre this way as food for any kind of cattle in the boxes or for horses; and by this system the labour is not so great as with the deep-rooting sorts, either for pulling when young or when lifting the main crop. There is, however, a great advantage in hand-pulling, because the food for cattle pays the labour; and as soon as the thinning has been done the remainder swell and grow a large size very quickly, and the crop is then quite safe from injury by the grub. We have, however, lost the whole crop by grub when the plants were set out whilst the roots were young and small. If the weather continues dry generally all the lands seeded, whether with grass seeds, Lent corn, or Mangolds, when rolled the last time, the land being rather coarse or rubbly—that is, not fine, but the clods being reduced to a small size, they, nevertheless, allow drought to enter and delay the vegetation and growth of any small seeds. To obviate this let the last rolling be done with the ring roller, and, if necessary, two different ways. This will press the surface and shut out the drought, whereas a smooth roller does not answer such a good purpose when the surface clods are hard and tough.

Hand Labour.—Dung-carting from the yard or heap will now be going on if applied to Mangold, Cabbage, or other root crops, because the dung deteriorates very much unless laid out when made or as soon after as required for use. The men will be engaged in filling and spreading the dung. It is a good time now to turn heaps of earth and dung as compost for laying on the pastures as fast as the hay crop is cleared off. If the weather is rainy find work for men and women too, the men mixing and preparing artificial manures in the manure store, and the women rubbing and preparing Carrot seed, &c., for drilling. Planting Cabbages should now be done, and our plan of doing it bids defiance to dry weather, because the men use light spades introduced at an angle of 45°, the women following, inserting the plants at the back of the spade, and boys to fetch plants. In this way the roots of the plants are buried deep in the soil, where they find moisture to sustain them, without dry dust from the surface running in, like it does when planting with the setting stick; in this way we have never known the plants to die in the driest of weather.

Live Stock.—On the vale farms, where it is customary to purchase sheep in the autumn for consuming the roots grown on the farm, we foresee that this system must be altered in anticipation of a foreign supply of frozen meat from our colonies, &c.; and the breeders on the hill farms are sure to have their profit on breeding if any, whereas the feeders on the vale farms will not be able to make feeding for mutton answer their purpose. We therefore advise them to turn breeders as well as feeders, and keep a summer stock of ewes suitable to the land. The early lambing Dorsets and Somerset horned ewes answer well in some dry soils; early Dorset Downs on some farms for the feeding of early lambs to fall at Christmas. Later stock, such as the Oxford or Shropshire Downs, will answer upon some of the midland districts, for they year a large increase of lambs; and if the ewes are bought poor in the spring or just after shearing-time, they can be run with the rams to great advantage, as so many can be kept in the summer and autumn and folded on the arable land. We find that they gradually improve in condition in this way, and become better stock than we can buy at the autumnal fairs except at a price leaving little or nothing as profit. With respect to horned cattle, if we can only get the country free of foot-and-mouth disease, the farmers who require cattle for winter feeding should breed them. We will refer to this matter another time.

OUR LETTER BOX.

Drag for Land (Trike).—In reply to your inquiry as to our recommendation of an implement which ought entirely to supersede the old wooden-framed drag, we name Howard's improved self-lifting drag harrow as the most effective implement yet invented, inasmuch as it can be raised out of work by the power of the horses. We advise you to apply to Howards of Bedford for an illustration and price of this implement if they have no agent in your district. The very curious instance of a cat rearing a young Rabbit shall be handed to the Editor of *Poultry*, as suitable for insertion in that paper.

REMARKS

27th.—Cold and showery till 6.30 P.M., fair after.
28th.—Fog in the morning (dense in the City), fair later.
29th.—Fog in morning and again after 3 P.M.
30th.—Foggy early, afterwards fine with bright sun.
1st.—Fair; sprinkle of rain at 5 P.M.; windy evening; rain from 8.30 P.M. till midnight.
2nd.—Dull; rain from about 4 to 6 P.M.
3rd.—Heavy rain at 8.50 A.M., and slight showers up to 6 P.M.; fine evening.
Temperature rather higher than in the previous week, and still below the average
There has been frost on the grass on four days of this week.—G. J. SYMONS.

SUMMER NOTES ON THE VINE.

THE present is an important time in vineries. Early Grapes are developing fast, and late Vines are now producing their shoots and giving their cultivators daily pleasure in watching for the bunches and comparing them with previous crops. It is always gratifying to find one bunch or more on each shoot, and when this is the case a crop may be relied on, but when several shoots develop without a bunch it is most unsatisfactory. This sometimes happens with amateur and professional growers in the case of certain varieties. Duke of Buccleuch and Gros Guillaume are frequently shy formers of bunches, and when very closely pruned many of the shoots come bunchless; but a certain remedy for this is to prune on the long-spur system and allow from 6 inches to 1 foot of the shoots to remain at pruning time. It will then be found that many bunches are produced, especially near the end of the old wood where the buds were more prominent and better ripened than close to the main stem. When the shoots are left as long as we have just indicated many more young growths will appear at this time than there is space for, or, indeed, than are required, and those not wanted should be broken away at the union with the old wood. This should never be delayed, and only the best shoots with the finest bunches must be allowed to remain. Very weak Vines should never be closely pruned, as this invariably causes them to be shy in forming bunches. Vines, too, recently lifted, transplanted, or disturbed at the root in any way are often shy in fruiting, and close pruning should not be practised in their case, but they should be encouraged to produce strong yet sturdy laterals.

Disbudding must have constant attention, and this is seasonable work at the present time. When we have had Vines with long spurs we have often allowed the shoot which pushed at the extreme end to remain as the fruit-bearer, and the one nearest the old stem was stopped when 4 inches or 5 inches in length; which caused it to thicken and make good wood for bearing fruit the following season. This is also a good way of keeping the spurs within bounds. Superfluous Vine shoots should never be cut off, as this causes more leaves to be formed behind the cut and more superfluous matter will be produced, which is no benefit to the Vine, but, on the contrary, injurious.

In all cases where shoots have to be taken away, they should be wrenched off with a sudden but gentle jerk from the base, and they will come away without the slightest injury to the Vine. Allowing too many shoots and leaves to remain is a great mistake, not by any means uncommon. They retard development of wood and fruit, and injure the Vines for the following year. That should always be kept in view, and when the foliage is crowded throughout the growing season and the superfluous growths are only thinned out late in the autumn in the hope of atoning for past neglect nothing but disappointment can follow, for by such means healthy Vines and superior Grapes cannot be produced.

Small spindly bunches, which have an uncertain appearance as to whether they will form berries or not, and end by producing a few large ones and a great many small ones, prove very conclusively their dislike to overcrowding, as light and air will always insure a uniformity in the berries, especially in late Grapes, at this season. From this it will be understood we do not advise allowing all the shoots to grow until the berries have been formed in order to see which are the most perfect, but we strongly recommend many of the weakest and all which it is quite evident will never be wanted to be taken away before they have developed. At present we have several one-year rods of Alicante, Gros Colman, and Golden Queen starting into growth. They are about 12 feet long each, and there are two shoots coming from almost every eye. One of these is strong, the other much weaker, and the latter is rubbed off before it is 3 inches long. This must throw strength into the other, and it certainly avoids crowding, which is, perhaps, the greatest of all evils in Grape culture.

Not very long ago it was a common practice to plant Vines at the beginning of the year, allowing the rods to extend to the top of the house. They were cut down to 2 or 3 feet from the bottom the following winter, and taken up again the second summer, again cut back the second winter; a few bunches were taken from them the third year, and a light crop the fourth, then followed a full one. Such work now-a-days is out of date, and rods 10 feet and 12 feet long are made to bear a bunch to every foot or so before they are well over their first birthday, and hundreds of growers are annually proving this to be satisfactory practice. This "system" is in my mind always associated with the late Mr. Pearson of Chilwell, who conducted many successful experiments in his extensive vineries near Nottingham long before the present Grape-growers commenced their experiments.

only be manner fruiting long young rods, however, can the can done successfully by paying the utmost attention to trainedes when they are being formed. They require to be shadin so far apart from each other that there will be no Youngg or obstruction of the light from the main stems. Young canes always emit many side growths, and these if allowed to grow will soon form a mass of twigs and leaves, and prove injurious to everything under them, but if these are stopped two joints from the main stem the best results will follow. Some growers dislike to stop the leaders in the case of young Vines, but allow them to extend even to hanging down the back wall of the vinery, reaching quite to the path and even trailing over the surface of the border. Never having appreciated the advantage of such liberal treatment we stop our young rods as soon as the top of the house has been reached, and they are never allowed to go farther. When stopped in this way they become very much thicker on the part which will bear the fruit than they would do if allowed to grow unchecked, and we think stoutness of cane and boldness of buds go for something.

The majority of Vines are making a great quantity of young wood just now, and all should be examined once weekly at least to regulate and restrict the shoots. The danger is always in allowing too much wood to be formed and too many leaves to shade the growths which will produce the fruit next year. The rays of the sun should penetrate between the leaves of all Vines and shine right into the interior of the house. Nothing will make the Vines more robust, healthy, and fruitful than this. As neglecting to thin and regulate the wood and leaves are hurtful to the Vine, so is neglecting to thin the berries injurious to the bunches. They should always be thinned before they have become a firm mass, and this they will very quickly do at this season. Those who do not feel confident in thinning them should go over them all twice, removing a few the first time, and as they become larger and it is seen that they are going to swell well more should be taken away.

As regards watering, no fruit-bearing plant requires so much as the Vine. If the borders are well drained it is almost impossible to give them too much, and in any case the roots should constantly be in a moist condition as long as the wood and fruit are developing and the leaves are green.—A KITCHEN GARDENER.

HARDWOODED GREENHOUSE PLANTS.

THE excellent article by Mr. Bardney on winter-flowering Ericas in the *Journal* of April 17th suggests further consideration and discussion of the extremely handsome class of Australian, or what were once called New Holland plants, that require in many respects treatment similar to the Ericas, and, like them, appear to be sadly neglected in private gardens. As the present is probably the most suitable time for cutting back or repotting many of the winter and spring-flowering species, a better could not be chosen for bringing a selection before your readers, together with some remarks on their cultivation. It is to be hoped that others will contribute information which may induce new cultivators to start, if only with a few healthy plants, and advise those who have not hitherto succeeded satisfactorily to buy again. If they will give careful attention to potting and watering success will probably be attained, and they will be assisting to again popularise such valuable plants for greenhouse and conservatory decoration.

Many are well adapted for culture in small pots, and although perhaps the majority flower in spring when there are plenty of other plants available for decoration, yet for beauty and interest hardwooded plants seem to stand out conspicuously, and to have an advantage over their softwooded associates. Not a few are, moreover, profuse bloomers, and are invaluable for cutting. Probably the greater ease with which softwooded plants are grown, and the extra attention given in raising new and improved forms of late years, have caused the great neglect of the other class, or it may be their merits are not sufficiently well known. Certainly there is but little demand for the latter at present, and some nurserymen seem almost to have discontinued their propagation.

The flowering season may be prolonged over a lengthened period by growing different genera and species that succeed each other. Thus Acacias, Diosmas, Eriostemons, Boronia megastigma and B. tetrandra, Tetratheca hirsuta, and Adenandra fragrans flower in winter and early spring. Epacris microphylla, a beautiful compact species with pure white flowers; Aotus gracillima, a slender-growing shrub thickly set with brown and gold-coloured flowers, extremely pretty; Pimelea elegans, Polygala Dalmaisiana, Hibbertia Reedii, Oxylobium ellipticum, Boronia elatior, and B. polygalifolia are in good condition just now, or in some cases just past their best. Succeeding these are Pimelea decussata and Dillwynia ericoides, which are just opening their buds. Bauera rubioides, Muraltia Heisteria, Grevillea Thelemanniana, and Tetratheca verticillata may be said to continue in flower as long as the plants are growing.

The whole of these, and many others of a similar nature, require the most careful attention in the selection of soil, in potting, and watering. Fibrous peat, neither boggy nor spongy, with sharp silver sand are required for all. In addition we used some loam last year, particularly for the Acacias, and having considered it advantageous have again used some this year. Most of the plants named above require cutting over much in the same way as Heaths, and the period when this is done is the most critical in the year with them. They should be kept close when at this stage, but if possible free from fire heat, provided the day temperature does not fall below 45° or the night 5° less. Slight syringings and supplying very little water at the roots is apparently the best plan to induce them to break, and after this repotting should be at once proceeded with. Those in bad health must have the old soil removed and the plants placed into smaller pots, while those healthy and having good roots should have a moderate shift. Pots 2 inches larger are in most cases sufficient, the balls of roots being retained almost intact if in good condition, but reduced if otherwise and returned to proportionate sizes. Pot firmly without burying the stems, again place the plants in the same quarters, and slightly shade them from bright sunshine. They will not require water at the roots for nearly a week, but should be kept close and syringed once or twice daily until established, when air may be gradually admitted.

We prefer shading from bright sunshine with thin material during the summer to prevent the roots being scorched. It is, however, important that it should be discontinued as soon as the hottest weather is over, and full exposure to sun with plenty of air given during the autumn. Without thoroughly ripened growth in this, as in so many other cases, free flowering cannot be insured. Rain water is much preferable for watering, as it is free from lime. This ingredient is a very destructive one to any hardwooded plant of the

class under notice. Where rain water cannot be obtained, and other has to be used, it should be exposed for some time to the sun and air, or have a small bag of soot placed in the vessel, which greatly assists in softening it. Nearly all the water in at least the southern parts of England has a certain portion of lime dissolved in it. Perhaps that from the pipes of the water companies in and around London is the worst for watering plants.

I should advise comparative restriction in the size of pots used. Hardwooded plants have very small roots, and they generally keep much healthier if they are somewhat restricted. Many form useful little plants and flower freely in 60 and 48-sized pots. Acacia lineata, A. armata, A. longifolia, and probably the best of all, Acacia Drummondii, are admirably adapted for flowering in these sizes. In addition to those plants already enumerated I would strongly recommend the following as being worthy of attention and cultivation. Goodia lotifolia, free-growing and very floriferous; Hedaroma tulipifera, H. fimbriata, Eutaxia myrtifolia, and Dracophyllum gracile.

Figures and descriptions of many of the above-named plants appeared in the *Journal of Horticulture* last year. Nearly all of them are natives of Australia and New Zealand, but some are from the Cape of Good Hope.—J. G.

CARROTS AND THE CARROT MAGGOT.

A CURIOUS fact regarding this came under my notice last year in a garden where the maggot annually destroys every Carrot with the exception of the Early Horn varieties, which are generally used before that dread insect has had time to attack them. All the Carrots comprising the main crop (and they were sown in different parts of the garden) were completely destroyed in a very short time, and that immediately after they were thinned, the roots at the time being about the thickness of a man's finger. On the first appearance of the enemy the ground was heavily dressed with soot, but this evidently had no effect, as the ravages were continued until the whole crop was destroyed with the exception of the ends of two or three rows which had inadvertently been left unthinned. The treatment given to the whole crop was similar in every detail except that these few ends were left unthinned; and strange as it may seem, these were left quite uninjured, while the others were entirely destroyed. What reasons can be assigned for this I cannot say, but would it not be worth while leaving a few unthinned until strong enough to resist the attacks of such a dire enemy? Have any readers of the *Journal* had similar experience?—CALEDONIAN.

"BIG" ROSES.

"HAVE you seen Her Majesty? No? Well, go at once to the far end of the tent. It is a most wonderful Rose." These words were addressed to me by an intensely excited friend on the 4th of July last year, just as I had finished my part in the judging at the National Rose Society's South Kensington Show. I followed my friend to the stand of cut Roses presided over by that successful raiser Mr. Bennett of Shepperton. Certainly, I was able to endorse my friend's opinion, for Her Majesty, as shown then and there, was a most wonderful Rose. Yes, a wonderful production, but to my mind a splendid monstrosity. The worth of many of Mr. Bennett's pedigree Roses no true rosarian would now dispute, and the singular beauty and refinement of some of them is in so great a contrast to Her Majesty that I, for one, can only believe that the raiser looks upon this one as a monstrous curiosity, and Mr. Bennett is so true a rosarian that he will not allow "his latest" to be distributed in this country, thinking her more suitable for England's big daughter on the other side of the Atlantic!

But my object in writing to the *Journal of Horticulture* is not to denounce this marvellous production, for it will be useful for walls, but to enter my feeble protest against this modern rage for size in Roses. The ladies do not like these "big 'uns," and surely their taste is not to be gainsaid. I heard many and many a remark last summer at the different shows, such as, "What a big coarse thing! I don't like it at all." Mr. Cant's Souvenir d'Elise was denounced by hundreds; and though it was not quite so large a bloom as the one of the same variety which occupied the premier position the year before, yet it lacked the colour and finish of the 1882 flower. To my mind, we are making a great mistake in this craving for size. Take up the ordinary nurseryman's catalogue, and in the descriptions of some of our most beautiful Roses is added in each case a sort of apology for a deformity (?). Mons. E. Y. Teas, Mrs. Laxton, Duchess of Bedford, Duke of Teck, Madame Noman have one and all heard the nurserymen's wail of regret, "Ah, how perfect you would be if only you would grow and get fat!" And yet I firmly believe that 75 per cent. of exhibitors of the queen of flowers, had they not been coached into this craze for size by the bad example of successful exhibitors, would in their hearts prefer the form and beauty of some of the above-mentioned

varieties to the size and awkwardness and "flotheriness" of some modern favourites. I do hope some of our nurserymen will this summer do what Mr. Cranston boldly did at the first Sheffield National Show. He put up Madame Noman for twelve of any light Rose, and was first; and yet he told me afterwards that he thought the Judges must have lost their heads (and hearts too) over the pretty things. But, I ask, are we to give all our prizes to Flemish cart horses, and reserve none for the graceful thoroughbreds, not to speak of the taking elegant little pony?

And what about Teas? I remember two or three years ago Mr. Prince, on seeing a huge but well-formed Anna Ollivier in my stand, saying, "You gentlemen make a mistake in going in for large Teas; you thereby spoil your stands." And, without wishing to detract from the excellence of the Teas as shown at South Kensington last July, yet I failed to see enough of the loveliness and—what should be—the sweet innocent look of *Rosa indica odorata*. We saw too much of the fully developed matron (and grand she was), but in some stands you looked in vain for "sweet and twenty." The question that troubles me is this: Are we really improving the form of the Rose if Her Majesty is to be the ideal type? I think not, and though many exhibitors and the trade will not agree with me, yet I shall have the support of the discriminating mass of the lovers of our favourite flower.

Mr. George Paul, in his catalogue, speaks of one of his Cheshunt-raised Roses as "not large, but a neat front-row flower." I presume that Her Majesty would go to the back row, but I shall be curious to see how she holds her position even there.—J. A. W., Alderminster.

SPECIAL SOCIETIES.

AT page 344 of your issue of the 1st inst. your correspondent, "D., Deal," tells a story transparently intended to reflect both upon my pecuniary position and personal character. He says:—"Some time before Mr. Dodwell removed to Oxford I gathered from him that he was in much trouble and anxiety owing to pecuniary losses and a threatened action for libel. Some days after, in thinking over our conversation, it suggested itself to me that it would be a graceful and acceptable thing to present him with a testimonial on the ground of the benefits he had conferred on floriculture; but feeling that I was not a sufficiently old friend to put myself at the head of it, I wrote to Mr. Charles Turner, who cordially approved of it, and warmly took it up."

I protest against this dragging of matters purely personal before the public. It is as destructive to honourable journalism as it is of individual right. I seek no immunity from criticism or censure, whatever its severity, which the performance of public duty may call, or seem to call for; but I protest against the degradation of controversy by attempted reflections on character and position; and I protest on public grounds, for these shameful things do not touch me to my hurt, whatever they may do to your correspondent.

As to the facts. The story of the conversation told by your correspondent is an absolute myth. He never was a confidant of my private affairs, and I never at any time made reference to them either in conversation or by letter, save as a consolatory rejoinder to some complaint of his. It is true that by the bad faith of a business connection I did lose virtually the fruits of the labour of my life; it is true also that for daring to vindicate my good name, as one of the incidents of my misfortune, I was threatened with proceedings for libel, but the matter ended in threats, and the evil inflicted upon me recoiled with ruinous severity upon the wrong doers. But this occurred in July, 1878, and, as I was informed, no mention was heard of any offering to me until after my announced departure from Clapham in September, 1881. Your correspondent's description of that offering also materially differs from that given me by others, but this is of small account. What is of account, of paramount account in my judgment, is, that he should be allowed to exercise his habit of attacking men or things under disguises more or less misleading to the uninstructed, in your columns, and whatever the subject, dragging in elements which envenom but never enlighten the controversy. What answer is his story of my pecuniary losses to the charge of my being a nurseryman, which he says I assume he made against me under the signature of "Fair Play?" Let him come into the open, and there shall be no question of evidence, and I shall have no hard words for opinions however adverse, openly expressed, and clearly the result of conviction, however mistaken; but as long as I can hold a pen or speak a word I will not cease to denounce anonymous detraction.—E. S. DODWELL, Oxford.

[We print Mr. Dodwell's letter verbatim, with the observation that his floral dynamite is harmless, and hence his references to ourselves, whatever may be his object, have no effect whatever. We have received a letter from "E. R. N.," founded on the false assumption that "D., Deal," committed a breach of faith in his communication on the page referred to. This Mr. Dodwell emphatically disproves in the words—"he, ('D., Deal,') never was a confidant of my private affairs." Mr. Dodwell frankly and openly made his friends acquainted with his circumstances. He made no secret of them in conversation, and

he received, as he knows, sympathy from ourselves and from others. After the publication of Mr. Dodwell's speech delivered at the Auricula Show, and a still more trenchant circular in reference to him, "D., Deal," felt himself compelled to show that, instead of being animated by personal enmity towards Mr. Dodwell, he had acted as a friend in disguise. "An Amateur" has also written to us under the mistaken view that "D., Deal," was Mr. Dodwell's confidant, and concludes—"If your correspondent 'D., Deal,' wishes to promote the interests of floriculture, he can easily do so. No better proof of his ability in this respect could be afforded than his able and interesting review of the late Auricula Show in your last number. In this way he is amply qualified to give us pleasure and instruction, but emanations like that at page 344 are only calculated to give pain to everybody."

Mr. Dodwell has fired his shot and ought to be satisfied. Whether he is or not, we cannot allow any more to be said on this purely personal matter, which has grown out of a very proper discussion connected with special societies. On this subject we shall be pleased still to offer space to those who wish to continue it, but we firmly decline to give publicity to any mere personalities. It is on this account that letters from three other correspondents are not inserted, two of which disapprove of Mr. Dodwell's action, and one sustaining it. Letters that are not suitable for insertion in the columns of the press can be printed and circulated through the post.]

WULFENIA CARINTHIACA.

OF the numerous alpine plants now at the disposal of the lover of these floral gems there are not many possessing greater claim to atten-

Fig. 89.—*Wulfenia carinthiaca*.

tion than this beautiful little plant. To some of our readers the *Wulfenia carinthiaca* is probably an "old familiar face;" but it is much less extensively grown than might, perhaps, be inferred from the mere date of its introduction. In the front ranks of the mixed border its spikes of bright blue flowers produce a charming effect, especially when grown, as it may be, in a good patch, or if several plants of it are grouped together. It may be termed a spring flower, for it usually commences blossoming in May and continues in bloom until July.

The *Wulfenia carinthiaca* is a perennial plant of dwarf habit, its foliage, which is all radical, not exceeding 6 inches; the flower scapes, however, often grow to the height of from 12 to 16 inches or more before the blossoms are all expanded. The leaves are ovate, blunt, with doubly crenate margins, and when full grown are spread flat on the ground; the small leaflets attached to the flower scape are more acute and sessile, with their margins rolled back.

The spike of flowers is at first drooping, but afterwards becomes nearly erect, though there is generally a slight inclination to one side. The flowers are bright blue, with a yellow throat, on short peduncles, closely arranged, and are somewhat remarkable for their oblique position.

From the character of its natural habitat it will be readily inferred that the *Wulfenia* is an excellent rock plant, but it will not endure full

exposure to sunshine, neither will it flourish if allowed to suffer from drought; a partially shaded situation should therefore be allotted to it. In the border it will succeed in any light rich soil free from stagnant moisture, which is injurious to it, especially in winter. In severe weather it should be covered with an empty flower pot, and in long-continued rains in winter the same precaution may be adopted with great advantage. In unfavourable localities it may even be advisable to pot it in autumn, and preserve it through the winter in a cold frame or turf pit, though this precaution will hardly be necessary south of the Trent. It may be increased by division in spring and autumn, and also by seeds, which it sometimes ripens. If a few of these are saved annually its protection will then be a matter of less importance, as young plants are readily raised from seed.—W. T.

GRAPE THINNING.

THIS is a subject about which it is difficult, if not impossible, to give precise directions, so much depends on the variety to be thinned and the degree of vigour in the Vine, but a few hints may be useful to beginners. A good set is of the greatest importance, as badly set bunches can rarely be thinned regularly. The time for thinning varies considerably. The Black Hamburgh may safely be done when the berries are of the size of Radish seeds, some others cannot safely receive their final thinning until the stoning is completed. Take a well-set bunch of Black Hamburgh as an example. The first thing to be done is to tie out the shoulders, which should be done more carefully than is often the case. Nearly a year ago I noticed in a large garden some fine bunches of Grapes which were completely spoiled by the careless way in which the shoulders had been managed. Instead of three ties to each shoulder there was only one, consequently the outer berries were hanging down, resting upon those below them, instead of being held clear by two or three neatly twisted pieces of matting. These bunches would have looked twice as large had the shoulders been well attended to. Moreover, allowing the berries to touch each other during the stoning period is a certain way of producing scald, and for this reason, if for no other, this matter should be carefully seen to. In some vineries the wires are not well placed for tying out the bunches, but a few laths split into suitable sizes and tied from wire to wire will remedy this defect.

Having carefully tied out all parts of the bunch requiring it, thinning may be commenced, it matters little whether from the top or bottom of the bunch. I generally begin at the bottom and work upwards. A piece of neatly twisted matting fastened round the stem near the bottom of the bunch is useful in moving the bunch about as may be required. All badly placed berries, especially those pointing inwards, may first be removed, and after that the condition of the Vines is the best guide. Vigorous Vines may be relied upon to produce large berries if freely thinned. I have been surprised at the size of the berries on a Vine of Lady Downe's, which from a peculiarity of the house always sets its fruit very badly. Thinning has much to do with the size of the bunch as well as the berry, careful thinning often making all the difference between good and undersized bunches. The berry at the extremity of the various parts of the bunch should always be left if possible, as their removal not only decreases the size of the bunch, but also robs it of part of its symmetry. It is difficult for beginners to thin Grapes with any degree of certainty without a year or two of acquaintance with the Vines producing them, and if they should require a second thinning let it be done as soon as possible after stoning, and very carefully, as the skin appears to be easily injured by any rough handling at this period.—T. A. B.

BORDER CARNATIONS FOR WINTER AND EARLY SPRING FLOWERING.

I HAVE never known these recommended for this purpose before, but they may prove very useful to some people, as the following facts will show.

A packet of mixed seed was purchased from a good firm at the end of September, 1882, and part of it was sown in boxes at once and placed in a gentle heat. As soon as the plants appeared they were gradually hardened off to enable them to stand through the winter in a cool house without any fire heat. Early in February, 1883, they were pricked out into other boxes, and when the season was far enough advanced were planted out in beds in the garden 15 inches apart. They grew freely, but did not produce any flowers during the summer. The autumn being a mild one, they commenced flowering in November, and at the end of that month several were taken up, and being large plants were placed in 9-inch pots and arranged for a time in a cool and moist house. As soon as they were well established they were removed to warmer quarters, where they had a minimum temperature of 45° to 50°. There they soon began to open their flowers, and have since yielded a large number. I counted over eighty blooms on one plant a short time ago in various stages of growth, and those left in the beds are now coming on fast, and promise a fine display of flowers soon.

Some may, perhaps, object to this system on account of some of the plants proving to be single varieties, and I may as well say only one has come single thus far, and it is not to be despised. I think if the seed is procured from a reliable source there need be no fear on this point.

Most probably the first week in October would be found the best time for lifting them.—W. H. DIVERS, *Burghley*.

DENDROBIUM DEVONIANUM.

AT one time this was considered a very difficult Dendrobe to manage, but I have always found it as easy to cultivate successfully as any other. Imported plants, after they arrive, often flower profusely from their long slender stems ripened in their native habitat, but to allow them to do this is a great mistake. Perhaps no Orchid is so much weakened by flowering as this, even when thoroughly established; but when first imported and flowered the stems are much shrivelled, and the growths the following season are weak compared with what they would be if the flowers were removed. This is not mere speculation, but has been practised repeatedly for the purpose of testing whether flowers exhaust the plants, and whether the previous year's pseudo-bulbs are of any service to the growths to be made the following year. Experience and observation therefore warrant me in recommending that the pseudo-bulbs be kept as fresh as possible, and the flowers removed from imported plants, or the growths will be poor.

This Dendrobe does best while growing in a rather close moist atmosphere where the night temperature ranges from 65° to 70°, with a rise by day of 10° or 15° from sun heat, or even 5° or 10° more when the house is closed in the afternoon. It does best in baskets suspended from the roof, and if allowed its growths will hang gracefully from the baskets; but here, while growing this plant is never allowed to assume its pendent habit, the stems being suspended as close under the glass as possible by means of matting. The reason I adopt this course is because I have found the growths possess greater solidity, ripen better, and in consequence flower more freely than when they are allowed to hang from the basket. Too much light cannot be given, yet the plants must while making their growth be shaded from direct sunshine.

D. Devonianum is not strong-rooting, and too much material about its roots is detrimental to success. It dislikes the soil used to become sour about its roots, and it should be renewed annually, the present being a good time. Employ for a compost three parts of sphagnum moss in a living state to one of peat fibre, with lumps of charcoal freely intermixed.

When the roots are advancing freely and the plant growing vigorously this Orchid will need more liberal supplies of water than any other Dendrobe with which I am acquainted, and if not applied and the plant liberally syringed it will soon become a prey to red spider, which quickly arrests its growth. The best preventive is a moist atmosphere, liberal syringing, and abundance of water at the roots. When this handsome Dendrobe is well grown it will make growths fully 4 feet in length, and if well ripened will flower freely for 3 feet of that length.

To show how freely and successfully it can be grown under the simple system detailed, it may be mentioned that a number of plants (imported) were purchased in February, 1883, for 3s. 6d. each. The majority started several growths, and each plant this spring has carried between 200 and 300 flowers.—W. B.

THE HERBACEOUS BORDER.

AT the early part of April the weather was bright and mild, but after the middle it was cold, and in the third and fourth week a keen north-east wind with sharp frosts at nights retarded, and to some extent injured, some plants either in their tender growths or their advanced bloom. Notwithstanding this some plants have flowered well during April, the most noticeable of which are still fine.

Iris nudicaulis.—The flowers of this plant are somewhat large, similar to a German Iris, the "standards" and "falls" being of a deep rich purple, the flowers being freely produced on a stem about 1 foot high, and with the foliage of a similar height have an effective appearance. It does well in ordinary soil.

Anemone stellata fulgens.—Too much cannot be said in praise of this scarlet Windflower. Its large dazzling flowers peeping above the ample foliage render it highly attractive, and it is one of the finest hardy plants for cutting in spring. It thrives in any ordinary soil, and once established takes care of itself, preferring a rich light soil well drained.

Anemone nemorosa bracteata plena.—This has the foliage of the Wood Anemone, and grows but a few inches high, the flowers white and double, with green bracts, the whole very interesting and pretty. This is best grown in light soil in a somewhat shady situation, but succeeds in the open border.

Dodecatheon Meadia.—The American Cowslip does well in any light soil somewhat moist but well drained, and its rosy-purple flowers, borne in umbels of a dozen or more each on a stem about a foot high, have an elegant appearance. There are numberless varieties with flowers varying in colour from white to crimson. All are hardy.

Corydalis nobilis.—This has handsome, spreading, much-divided, Fern-like foliage, the plant being very compact in habit, the flowers all borne on arching stems just clear of the foliage, the colour being a rich golden yellow with a black centre, giving the plant an attractive appearance, and in the ordinary border it grows rather more than a foot high, and certainly is one of the grandest of spring-flowering plants. In a moist soil, free, however, from stagnant water and somewhat shaded, it grows more robustly, but does not flower so freely or finely as in an ordinary border of light rich soil well drained. Where interesting plants are cherished this should find a home, as it certainly is the finest of the family.

Dielytra eximica.—One of the best of spring-flowering plants, its foliage and flowers alike are useful for cutting, its graceful flowered sprays being fine for vases. As a plant the pale green much-divided Fern-like foliage, and its racemes of pendent rosy-purple flowers, render it a charming border plant, doing well in any light soil well drained, and whilst *D. spectabilis* is cut off by the frost to the ground this is not injured at all either in foliage or flower. It grows about 12 to 18 inches high, and is spreading.

Saxifraga Wallacei.—A really good and useful plant. The large white flowers are borne in upright panicles, being useful for cutting. It grows about 12 inches high, and does well in an ordinary border of light soil. It should find a place in every garden, as it is so easily grown and so free-flowering and effective.

Mertensia virginica.—Very effective from its stems of 12 to 18 inches high, terminating with clusters of long tubular flowers of a deep purplish-blue, and although a moisture-loving plant it does well in an ordinary border if given some leaf soil or a peaty soil with slight shade.

Iberis gibraltarica.—A bush of this, 3 feet in diameter and 18 inches in height, clothed with large compact heads of white flowers tinged with red, is very effective. It is useful for cutting, as the plant commences flowering early and continues right through the summer. It is the largest and finest of the evergreen Candytufts, and requires a light soil well drained, and then is perfectly hardy, otherwise it requires a warm situation. It is readily increased by cuttings, so that a few plants can be kept in pots through the winter in protection to meet any casualties.

Centaurea montana alba.—The Perennial Cornflower, from the mildness of the winter, has grown all the winter, and was not injured to any extent by the frosts of April, during which it commenced flowering, being now over 2 feet high, and having numbers both of flowers and buds, which last for a very long time and are useful for cutting. It will grow anywhere in an open situation, but likes a light or well-drained soil, and by cutting away the old flower-stems will give a successional supply of flowers through the season.

Phlox Nelsoni.—In a light well-drained soil this is an effective border plant; its moss-like foliage decked with the snowy white flowers render it useful as a front row plant.

Adonis vernalis.—The large bright yellow flowers of this plant are very showy, and supply one of the best yellows in spring-flowering plants. It takes some little time to become established, and it is only as such that its merits become apparent. It only grows a few inches high, and does well in an ordinary border of light soil enriched with leaf soil. It ought to have a place in every garden, and in the mass is quite charming.

Gentiana verna.—The bright blue flowers of this are lovely, it requires a good loamy soil, which, however, must be well drained and never allowed to become dry. It does fairly well in the open border if kept well supplied with water in dry weather.

Caltha palustris flore-pleno.—The double Marsh Marigold is very showy from its large deep green glossy leaves and numerous large, double, golden-yellow flowers, and does exceedingly well on a north border or any situation, preferably a damp one, in good rich deep soil.

Narcissus poeticus ornatus.—This flowered freely during the month, and where cut flowers are in request ought to be grown in quantity. *N. biflorus* commenced flowering at the close of the month, and is very useful for cutting.—G. A.

HISTORICAL JOTTINGS ON VEGETABLES.

ARTICHOKES.

To many readers it might seem a very plausible explanation of the name "Artichoke," to say that the last syllable at least refers expressly to a portion of the head of the plant, by which, undoubtedly, even when it is boiled, an eater thereof might be choked; and we may, indeed, accept it as a fact that persons have been choked through an incautious attempt to swallow this, although we fail to recall the name of any individual which has been chronicled in connection with the circumstance. "Artichoke," however, is thought to have come to us by way of the French *artichaut*, and that some authorities derive from an Arabic word, *harchiaf*, variously spelt; and others believe it to be a perversion of the Greek *artytikos*—i.e., "fit for seasoning," which is applicable enough. And both Greeks and Romans showed a remarkable partiality for the Artichoke, which has a history that extends back to the century before the Christian Era, or farther still.

It is uncertain whether the countries which are the first mentioned by old authors as yielding Artichokes are really the natural localities of the species, which is, in truth, but a sort of Thistle, a fact upon

which Pliny sagaciously comments, deeming it a strange thing that Roman aristocrats should condescend to such asinine food. Not only so, but they squandered upon this vegetable, said he, about thirty thousand pounds yearly (in our money) buying it from the north coast of Africa, or from islands in the Mediterranean. As the Greeks also appear to have had their Artichokes from these islands and regions on the borders of that sea, we suspect that thereabouts was the home of the wild Artichoke that first supplied plants to gardens, and it evidently flourishes in a warm, rather equable climate. And the Romans probably fancied best those Artichokes raised out of their own land, since Pliny implies they were not much grown in Italy, though he gives a few cultural notes, advising the application of some manure, and remarking that plants should not be transplanted when a cold wind prevails. The Roman gardeners used to sow the seed at the end of February. Amongst the ancient virtues were attributed to the Artichoke which are no longer assigned to it. The expressed juice was applied to the head in cases of baldness, and the root was boiled down, the liquor so made having the repute of acting as a stomach invigorator. As the vegetable could not be obtained all the year round, the head was preserved or pickled in sweetened vinegar, cumin seeds or other aromatics being added to spice up the liquor. By one of those laws which are characteristic of the Roman age of luxury and pride, the lower orders were forbidden to eat Artichokes.

And then, for many centuries, this plant seems to have been lost sight of, but about the middle of the fifteenth century some Artichokes were brought from the Levant to Italy by one of the Strozzi family. The Italians regarded it as a curious novelty, and an old author mentions having seen a few of them growing in a Venice garden some years subsequent to the above arrival, and it was cultivated at Naples, but not much known in Italy until the sixteenth century. Early in that century the Artichoke travelled to France, and thence to England, where a dish of the vegetable became one of the choice articles placed upon the table of Henry VIII. The yet extant records of the Royal expenses during his reign yield sundry entries concerning the purchase of Artichokes which were brought to and eaten at his palace in York Place, or what soon became known as Whitehall; or they were occasionally brought to the king as presents from the nobility, when of course a gratuity was bestowed on the bearer. These would be doubtless grown in some of the gardens attached to the palaces of the gentry about the suburbs. Gerard has figured the plant, but does not describe it, though it was probably cultivated by him in his Holborn botanic garden.

The first locality upon which we can fix definitely as one in which Artichokes were raised for the London market was an extensive strip of ground upon the bank of the Thames, which supplied a variety of choice vegetables to the costers and dealers for many years. This now forms a part of the South Belgravia district, but originally it was reckoned as belonging to Chelsea, being situate between that village and the city of Westminster. The oldest name given to the spot was "The Neathouses," from some buildings then occupied by the gardeners, and which are presumed to have got their designation from the manor of Neate or Nayte. It was land somewhat marshy, not much above the level of the river, and sheltered by the Surrey hills, also by the higher ground of Middlesex, therefore well suited for the culture of the Artichoke. We read frequently of these Neathouse gardens during the Stuart period. In the reign of Charles II. they were for a time the resort of citizens, who went to feed upon fresh vegetables or fruit at a place that produced them. A collector of the cries of London, who compiled his list in that reign, has set down this vegetable as one that was commonly cried, and his spelling of the word "hartti-cokks" is original.

Both the globe and the French or oval variety were known at the beginning of the seventeenth century, but it cannot be said that the Artichoke has ever been a favourite vegetable with the British people. From remarks on the subject made in works on gardening written for our ancestors, it seems that many of the plants were lost by mismanagement in the severe winters which have become a thing of the past. This, possibly, rather tended to discourage the culture of the Artichoke. Abercrombie insists upon the importance of "landing up" the plants in good time, and he adds that when there arose a need to replenish beds gardeners often found the young sets were difficult to get, and commanded a high price. The Channel Islands were, in the reign of William III., made to yield many fine Artichokes, and it was said the plan of manuring with seaweed, of course containing saline particles, favoured the growth of the plant. In some districts of Scotland there is still much manure of this kind applied to the Artichoke beds with evident success. Foreigners have, as a rule, praised the English Artichokes, so it would seem our moist climate yields them of equal or superior flavour to those produced on the Continent, where it is much more a leading vegetable than it has yet been in this island. The French are partial to them, eating them frequently at breakfast, also as a sort of salad, and uncooked, while they are young; and in many places the heads are pickled, somewhat on the method of the ancient Romans.

The Cardoon, nearly related to the Artichoke, by some indeed regarded as a mere variety, is of larger size, but it has never attracted much notice in England; therefore, needs only a brief mention. It is, however, grown freely for the table in several European countries, and the down is also carefully preserved to make therefrom an infusion for curdling milk instead of rennet. John Tradescant appears to have been the first Englishman who has anything to say about the Cardoon, and he told Parkinson the botanist that he saw (probably about 250 years ago) three acres of land near Brussels planted with this vegetable, the growers blanching the leaves to be eaten as Endive. It did not arrive here until 1683, the earliest cultivator being a Mr. Sutherland. It is a native of South Europe.

There is another plant popularly styled an "Artichoke" which belongs to a very different group, being a species in the Sunflower tribe. The tubers, not the heads, are eaten, hence the name of Jerusalem or ground Artichoke; the former is evidently a corruption of the Italian word *gerasol*. Prior to the discovery of America, where the plant has its habitat, it was of necessity unknown to the Old World. The French, about the time of Elizabeth, brought it to their country, and as for a time it was called the Canadian Potato, some confusion has arisen in consequence. It is supposed, however, that at an earlier date unknown, Italy had specimens of this Artichoke from Peru or Brazil, where in fact it is truly indigenous, and not in a cold region such as Canada. A London merchant, Mr. Franqueville, had two roots from France in 1617, and by degrees it was distributed throughout Britain.—J. R. S. C.

At a general meeting of the ROYAL HORTICULTURAL SOCIETY, held last Tuesday, Robert Hogg, Esq., LL.D., F.L.S., in the chair, the following candidates were elected Fellows—viz., Mrs. Edith Ames Lyde, Edwin George Ardley, Captain Brickwell, R.N., John C. Duke, William L. Ewart, Sydney Wynn Graystone, Mrs. Gardner, The Marchioness of Headfort, Mrs. Nutkins, Frank Price, Baron F. de Rothschild, Walter Hercules Short, William Urwick, Mrs. Frances Williams, and George C. Wylie.

— THE SALE AND ASHTON-ON-MERSEY HORTICULTURAL SHOW will be held in the Botanical Gardens, Sale, on June 19th, 20th, and 21st of the present year. This is the second Exhibition which has been held under the auspices of the Sale Botanical Society, and the former efforts having been much appreciated in the district, an Exhibition of much interest is expected. Eighty-three classes are provided, the prizes for plants ranging in the open classes from £3 to 5s.

— A LIVERPOOL correspondent fears "we shall have NO FRUIT THIS YEAR. We had 8° of frost one morning while the Pears were in flower, and 5° and 6° every morning for a week. My young trees have been full of bloom, but the fruit which appeared to set is all falling off. The wind has been piercingly cold, and the young tender foliage is scattered all over the ground."

— THE AUSTRALIAN ROYAL FERN, *TODEA BARBARA*, though rather scarce in European collections of Ferns, is a bold and handsome species, which grows well in a cool house. The finest plant in cultivation is that in the temperate house at Kew, which, when introduced by Dr. F. Mueller from Mount Macedon, Victoria, weighed 14 cwt. The huge stem is now about 4 feet high and as much in diameter, with strong fronds 5 to 6 feet long, and of a deep green shade.

— AURICULA CHAS. J. PERRY.—A correspondent writes:—"This Auricula is one of the most useful plants a gardener or amateur can have for brightening the conservatory at this time of the year. Its colour is violet-blue, it is very free, and forms fine trusses. Some people would wish to make us believe that the open borders and rockwork are the proper places to grow these old-fashioned flowers. So they are for the Alpines; but to have good blooms, the show and self varieties must have the protection of a cold frame."

— A COPY of "AMATEUR GARDENING" has been sent to us, and a very neat and attractive little paper it is. It is issued from Salisbury Square, and we believe is conducted by the Editor of the *Gardeners'*

Magazine. It does him great credit, and we say with him that "with seven papers to choose from, the man must be hard to please who cannot find one to suit his tastes and requirements."

— WE are informed that Mr. Thos. Lee, late foreman at Shirburn Castle Gardens, Tetsworth, Oxon, has been appointed gardener to T. Hopkins, Esq., San Francisco, California.

— A JOURNEYMAN wishing to improve himself on the culture of Vines, desires to know how Mr. J. E. Waiting managed to grow his BLACK HAMBURGH GRAPES ON THE BACK WALL OF HIS VINERY. He would like to know the height of the vinery at the back, also the size of the bunches that were grown to overlap each other; he would, indeed, be glad to know all the particulars to enable him to succeed similarly.

— WHERE large specimens of any choice variety of *IMANTOPHYLLUM MINIATUM* are grown some caution must be exercised in allowing them to bear seed, as it is surprising what an injurious effect it has even upon apparently vigorous plants. We recently saw a most valuable plant of the variety Martha Reimers which was killed by a heavy crop of seed. This, however, fortunately ripened, and abundance of young plants will be obtained, many of which will probably equal the parent in size and colour of the flowers. This plant was in robust health and received the most careful treatment, but it evidently could not endure the severe strain upon its energies.

— "R." wishes to know if *CESTRUM VESPERTINUM* is grown in England. "It is mentioned by some travellers on the Continent as being extremely beautiful in Spain and elsewhere, bearing a profusion of white flowers. *C. aurantiacum* I know very well, but a white-flowered species I have never seen, and should think it must be scarce if it really is in cultivation here. I understand that the plant has been determined by Mr. Benthams, so no doubt the name is correct. I should be glad to have some information about it."

— "CONSERVATIVE ROSE" writes:—"I am very anxious to procure names of BLUE FLOWERS—real blue, not violet or purple tinted. I shall be grateful to any of your readers who will help me dividing them as follows, under the heads of the seasons. I have collected a few plants, and desire to make a more complete collection. Spring.—Blue Hyacinth, Squills, Veronica, Gentians, *Myosotis dissitiflora*, and Irises. Summer.—New Blue Rose Harebell, *Convolvulus*, *Salvia*, *Ceanothus divaricatus*, *Centaurea cyanus*, *Aquilegia glandulosa*, *Delphinium formosum*, and *Lobelia*. Autumn.—Blue Pansy. Hothouse.—Blue *Cineraria*, *Achimenes longiflora major*, *Tweedia cærulea*, *Sollya heterophylla*, *Leschenaultia biloba*, and *Plumbago cærulea*. Any help will be gratefully received."

— RASPBERRY WEEVILS IN CORNWALL.—We learn from the *Cornish Telegraph* that the Weevil, *Otiorynchus picipes*, which played such havoc among the Raspberries a few years since, has again made its appearance, and the market gardeners are on the look-out for the mischievous little insect, which kills the fruit-bearing shoots by boring holes through them.

— BEFORE us are blooms of *CALCEOLARIAS* from Canon Babington Glendermott Rectory, Londonderry, who writes:—"I send a few blossoms of Carters' Victoria compacta strain of *Calceolaria*. The plants are wonderful. In shape, form, and colours the flowers are splendid. My gardener has been having all the neighbouring gardeners to inspect, praise, and, I would add, envy them." Beyond question the plants are well cultivated, otherwise such remarkable flowers could not have been produced. They merit high praise, some of them being 2½ inches across, full, smooth, bright, and diversified in colour. It is but simple justice to say that they are a credit to both cultivator and seedsmen.

— THE summer Exhibition of the LEE, BLACKHEATH, AND LEWISHAM HORTICULTURAL SOCIETY will be held on July 9th and 10th. The Society appears to be admirably supported, and we are glad to see so many special prizes offered. We also observe a prize of honour—namely, a silver memorial cup, presented by the President, John Penn, Esq., in memory of the late President, Dr. Carr, offered under the following conditions:—"The cup is the property of the Society after the formal presentation to the winner of the largest amount of prize money at the summer Show, it will remain in the custody of his employer. The gardener to have for permanent possession a silver medal, showing him to have been the winner for that year."

— In an elaborate article by Mr. D. Cannon on the "MINERAL

REQUIREMENTS OF FOREST TREES," which appears in the May issue of the "Journal of Forestry," a table of wood analyses of the principal forest trees is given. Wood of different ages has been taken, and the relative proportions of potash, soda, lime, magnesia, iron, and several compounds are fully stated. The table was, it appears, originally prepared by Dr. R. Weber of Bavaria, and has been also published in France. A cubic metre of each was taken, which is equivalent to about 37 of our cubic feet, and the amount of ash is given in grammes and English pounds or decimals of a pound. The following will serve as examples:—Beech, fifty years old, total ash 6 lbs.—potash 1.4 lb., soda 0.086 lb., lime 2.6 lbs., magnesia 0.62 lb., sesquioxide of iron 0.65 lb., sesquioxide of magnesia 0.71 lb., phosphoric acid 0.44 lb., sulphuric acid 0.13 lb., silicic acid 0.4 lb. Oak, fifty years old, total ash 12 lbs.—potash 1.55 lb., soda 0.32 lb., lime 8.84 lbs., magnesia 0.35 lb., sesquioxide of iron 0.077 lb., sesquioxide of magnesia 0.024 lb., phosphoric acid 0.45 lb., sulphuric acid 0.10 lb., silicic acid 0.26 lb. Birch, Larch, Pine, and Silver Fir are treated in the same way.

— "H. L." writes:—"Can any of your readers inform me if *CEREUS GRANDIFLORUS MAYNARDI* is in cultivation now, and where a plant could be obtained?"

— AT the meeting of the ROYAL METEOROLOGICAL SOCIETY, to be held at 25, Great George Street, Westminster, on Wednesday, the 21st inst., at 7 P.M., the following papers will be read:—"Note on the Proceedings of the International Polar Conference held at Vienna, April 1884," by Robert H. Scott, M.A., F.R.S., President; "Meteorological Observations on the Maloja Plateau, Upper Engadine, 6000 feet above the Sea," by A. Tucker Wise, M.D., F.R.Met.Soc.; "On some Results of an Examination of the Barometrie Variations in Western India," by A. Naylor Pearson, F.R.Met.Soc.; "Illustrations of the Mode of Taking Meteorological Averages by the Method of Weighing Paper Diagrams," by Richard Inwards, F.R.Met.Soc., F.R.A.S.; "Ten Years' Weather in the Midlands," by Rupert T. Smith, F.R.Met.Soc.

— WE regret to have to announce the death of MR. ALEXANDER JAMES MAULE, of the Stapleton Road Nurseries, Bristol, which took place on Monday, the 5th inst., at the age of sixty-three. Mr. Maule was the son of the late Mr. William Maule of these nurseries, and was the third generation of the family who carried on business at the same address. The Stapleton Road Nurseries, together with those of Durdham Down, were at one time the most important of the west of England, but the extension of the city, and the great increase in the value of land for building, combined to limit the extent of both establishments, and in the case of the latter a new nursery has been formed further in the country. Mr. Maule had of late years converted his ground into pottery works, for which the clay was well adapted. In the early days of the introduction of Indian Conifers and Orchids Mr. Maule's was a prominent name, with which *Cypripedium insigne* Maulei is intimately associated. Large consignments of seed of *Cedrus Deodara*, *Pinus excelsa*, *Abies Smithiana*, *Picea Webbiana*, &c., were frequently sent to the Stapleton Road Nurseries, and Mr. Maule was also successful in opening up communications in Chili for the importation of seed of *Araucaria imbricata*. One of Mr. Maule's most recent introductions was *Pyrus Maulei*, by which his memory will be perpetuated. Mr. Maule was a bachelor, and a man of a thoughtful and philosophic turn of mind. It was refreshing to spend an afternoon with him, and to discuss matters of horticultural or arboricultural interest, for he had always views on these subjects to propound which had at least the merit of freshness; and the man himself was of that loveable nature which always gave a zest to the time spent in his society.

— EVERY year the CALCEOLARIAS AT BEDFORD HILL HOUSE, BALHAM, are eminently worthy of notice, alike by the excellence of the varieties and the superiority of culture as displayed by Mr. Rapley. To say that they are equal to those of past years is saying about all that can be said, as it is not easy to imagine larger, smoother, finer flowers, several of them 2½ inches in diameter, and in not a few instances so numerous that it is difficult to see how they can expand. Still they find their way out of the crowd and form massive heads of great brightness in the yellow grounds, chasteness in those of a creamy nature, and richness in the glowing crimson self and mottled varieties that contrast so effectively with the finest of canary-coloured varieties, the conspicuously beautiful Cloth of Gold. But fine as the flowers undoubtedly are, it is impossible not to admire equally the sturdiness of the plants. Except for affording the flowers space for development no stakes would be needed. With stems as thick as the finger of the cultivator, and vary-

ing in height from 6 inches to a foot, they are quite self-supporting; still, a little tying-out is done for the purpose mentioned. The plants are grown in 5-inch, 6-inch, and 7-inch pots, the object being to display as many varieties as possible in the 100-feet-long house. It may be stated without any reserve that out of the great number there is not one inferior, and the excellence of the strain is rendered the more striking by the contrast that is afforded by a dozen or two of plants raised from a celebrated continental stock, and sent for testing and comparison. Mr. Rapley is to be congratulated at the success he has achieved by careful fertilisation and selection in establishing such a valuable strain of these exceedingly handsome greenhouse flowers, also on the skill that is manifest in the cultivation of the plants.

— MR. JOSEPH MALLENDER sends the following SUMMARY OF METEOROLOGICAL OBSERVATIONS AT HODSOCK PRIORY in April:—Total rainfall, 1.78 inch; maximum fall in twenty-four hours on the 28th, 0.35 inch. Rain fell on nineteen days. Total duration of sunshine in the month, 106.1 hours, or 26 per cent. of possible duration; three sunless days. Average velocity of wind, 7.6 miles per hour; it did not reach 400 miles on any day, and fell short of 100 miles on seven days. Mean temperature of the month, 44.0°. Maximum on the 3rd, 64.9°; minimum on the 23rd, 23.6°. Maximum in sun on the 22nd, 120.9°; minimum on grass on the 23rd, 21.0°. Mean temperature of the air 9 A.M., 45.7°; mean temperature of the soil 1 foot deep, 46.5°. Nights below 32° in the shade, 7; on grass, 16. During the first nine days of the month the temperature was above the average, but the rest of the month it was considerably below it, with north-east winds and showery weather. During the previous eight years only two Aprils had a lower mean temperature—viz., 1879 and 1881. It may be stated that the mean daily minimum is 7.1° lower than in January. There have been no heavy falls of rain, but a hailstorm occurred with thunder on the 28th. The total rainfall of the period is less than the last two years. The sunshine has been much less than in any of the previous three years. About 90 per cent. of our fruit blossom is killed on the Apple, Pear, Plum, and Gooseberry. Cherries have not suffered so much. Many Strawberry flowers have black centres. The Oak is at least fourteen days before the Ash.

— THE monthly general meeting of the NOTTS HORTICULTURAL AND BOTANICAL SOCIETY was held at the Mechanics' Institute, Nottingham, on Wednesday evening, May 7th, when Mr. E. Jenkins of Ratchiff-on-Trent read a very interesting and exhaustive paper on "Spring Gardening and Spring-flowering Plants." The chair was occupied by Mr. J. R. Meadows of Rock House, Basford, who exhibited a large collection of dried specimens of British flowering plants, which were briefly described by him. Mr. Samuel Thacker sent a remarkably well-grown plant of *Cypripedium barbatum* with very highly coloured flowers. Mr. N. German, gardener to T. B. Cutts, Esq., Malvern House, sent a choice collection of eut Orchid flowers, which were much admired, amongst them being a splendid spike of *Vanda suavis*. Mr. Walker, gardener to J. W. Lewis, Esq., of Hardwicke House, Nottingham, had a choice collection of eut stove and greenhouse flowers; whilst Mr. Argyle, an artisan Rose-grower, had a magnificent stand of Rose Cheshunt Hybrid, and for the purpose of illustrating his subject Mr. Jenkins, the reader of the paper, set up a large and choice collection of spring flowers, which had been sent by Mr. T. S. Ware of Tottenham and Mr. William Ingram of Belvoir Castle, and which were admired by all present. Mr. Jenkins in a very able manner commented at some length upon the great strides which had been made of late years in spring gardening, and instanced Belvoir and other places as showing what might be done with many plants which some considered to be almost worthless objects. He then gave a description of many spring-flowering plants which were suitable for town gardens, and the positions most adapted to the requirements of a large number of spring plants. At the conclusion of his paper he was accorded a very hearty vote of thanks.

— THE Committee of the above Society also offer the following prizes, given by Messrs. Pownall, Pearson, and Thacker, to be competed for by under gardeners, who are members of this Society, for an essay on "THE ROTATION OF CROPS IN A KITCHEN GARDEN FOR A YEAR," not to exceed twenty minutes in reading, to be illustrated by a plan. First prize, 12s. 6d. and the certificate of the Society; second prize, 7s. 6d. and the certificate of the Society. The competition will take place at the monthly meeting of the members at the Mechanics' Institute on June 11th, and will be decided by the members present. Intending

competitors must give notice to the Hon. Secretaries by Saturday, June 7th, of their intention to compete.

PANICUM VARIEGATUM AND ISOLEPIS GRACILIS.

In the above we have two very useful plants for decorative purposes, and no one having such work to perform should fail to grow a few dozens of each. A great recommendation is that they grow freely in any light sandy soil, and in a genial temperature; and they are so easily propagated that anyone in possession of a few plants may readily raise a large number. The *Panicum* is increased by cuttings, the *Isolepis* by division. They may be employed with effect in many ways. What, however, I wish more particularly to draw attention to is their suitability for growing in small thumb pots. They have a very pleasing appearance as a fringe to other plants, and for such a purpose they cannot be too largely grown.—JOSEPH RICHARDSON, *Calverton Hall, Notts.*

TYING DOWN VINE SHOOTS.

In the last issue of the Journal Mr. Young advocates tying Vine shoots below the wires; but desirable as that may appear, there are several objections to it, which in some cases, indeed, render it almost impracticable. In the first place, if the shoots are brought below the wire and the ties employed should break when the bunches are swelling, there is nothing to prevent the shoot breaking and the Grapes falling; whereas when the shoot is above the wire this would prevent any serious accident, even if the ties did break. Another matter of importance is that there is often great danger of breaking the shoots in endeavouring to bring them beneath the wires, especially if the growth is somewhat advanced before the tying-down is attended to. In some cases indeed it is quite impossible from the position of the shoots to place them under the wires. It should also be remembered that the chief danger of the shoots pressing up to the glass in the early stages, which tying down is quite sufficient to prevent, but afterwards the weight of the bunches will keep them down effectually. I have seen so many laterals broken in efforts to get them under wires, as advised by your correspondent, that I thought a word of warning might be useful to some readers.—V.

PRUNING ROSES.

LIKE "A. C." (page 345) I was for many years a firm believer in early pruning; so much so, in fact, that after the wood became matured in the autumn I could not withstand the temptation to prune such varieties as by experience I knew would be least likely to suffer thereby. The same operation was also practised at intervals through the winter season when the weather and other circumstances permitted, and very seldom indeed had I cause to regret having done so, by afterwards seeing either blackened shoots or deformed buds as the result of such practice.

This was, however, in the high and comparatively dry midlands, where the elevation was such as insured a continuance of a more uniform temperature and a far greater dryness in the atmosphere than I have found in the more variable valleys of the south. In these there is a far greater tendency in the Rose to produce early and more succulent growth, that is much more susceptible to injury than when grown in a more elevated position where the climate is drier and where there is a comparative immunity from spring frosts. With some assurance and much faith I ventured to follow the same practice for a few years after I became located in the south, but too frequent failures soon caused me to change my tactics, especially when I found by comparison that the results from the early and the late pruned plants were most decidedly in favour of the latter.

After several years' experience, and also after comparing notes with others similarly situated to myself, I can come to no other conclusion than that April-pruned Roses give, in such positions, at least much the best results. These notes apply more particularly to the treatment of standards, which must from necessity, so as to keep them within bounds, be pruned back annually, but in respect to dwarf Roses I much prefer unpruned pegged plants, whether for the purpose of garden decoration or for producing fine blooms for the exhibition table. These, if the buds be well thinned, give as fine and as perfect blooms as it is possible to produce either upon standards or upon hard-pruned plants, and they are not nearly so liable to be destroyed by early frosts as the young shoots are upon severely pruned plants.—W. C. T.

EXOTIC PLANTS IN CORNWALL.

THE similarity of the flora of this part of England to that of the Channel Islands and also of West Europe is very striking. A remarkable fact in connection with West Cornwall, or, indeed, of the entire county, is the singular absence of any extensive tracts of woodlands. Plants from the Cape of Good Hope and South Australia seem to thrive there with quite a native vigour. Japanese plants are singularly "at home." Camellias, Rhododendrons, and Azaleas may be specially mentioned as attaining tree-like size under ordinary cultivation. Very beautiful are the three splendid "specimen" Camellia trees during the very early months of spring at Tredrea, near Penzance, the seat of Robin Bolitho, Esq. The very large specimen tree at Penalvern, near Penzance, is said to be the first ever brought into Cornwall, or, at the least, the western part of the county. A very famous wall of Camellias is that at the residence of Geo. Williams, Esq., Scorrier. Lamorran in the east and Trewidden in the west are

famous for their very fine collections of Rhododendrons, which assume gigantic proportions.

The severe winter 1879-80 killed many important exotic plants. Many more suffered great injury. Among succulent plants *Aloe Barbarea*, *A. barbadensis*, *A. ciliaris*, *A. dichotoma*, *A. plicatilis*, *A. socotrana*, and *Agave undulata*; *A. filifera* and *A. mitris* were, I am informed by Mr. Tyerman, killed in and around Tregony. Palmaceous plants, such as *Chamaerops humilis* and *Fortunei*, *Corypha australis*, and several others were severely damaged, and in many instances killed, but escaped pretty well at the Scilly Islands. Several species of *Araucaria*, including *excelsa*, *Cookii*, and *Bidwellii* were also killed.

Plants which are quite hardy at Scilly differ very much from those of the mainland, and more particularly the more eastern part of the county. Some beautiful *Dicksonias* have withstood the severity of several winters very well indeed. At Scilly and at one or two favoured localities around Penzance it is not much injured, but at Hayle (about twelve miles from Penzance), a large plant, some several feet in height, was killed. As a general rule this Fern requires protection from winds. Next to the Ivy and *Ampelopsis* no climber here flourishes in so luxuriant a manner as the common Passion-flower (*Passiflora cærulea*); through mild winters it is evergreen, the leaves presenting a pleasing contrast to the numerous deep yellow Orange-like fruit. It thrives well within a short distance of the sea, where, however, it becomes perfectly deciduous.

The Heaths are well at home there as border plants in a peaty soil. The one which thrives and continues in flower from the early part of December until early summer is *Erica carnea*; *E. ciliaris*, *E. gracilis*, and *E. mediterranea* I noticed in flower at Christmas a year or so ago. Although preferring a peaty compost, most of the hardy sorts do very well in a sandy soil. Naturally the *Veronicas* are perfectly at home; but I would call attention to not only one of the best, but one which flowers continually throughout winter and spring—it is *V. Lindleyana*. The habit of the plant is very neat, and the racemes of flowers are white with a bluish tint. Much-neglected and very hardy plants are the several species of *Cotoneaster*; well-trained plants of *C. microphylla* are pretty objects throughout the winter, having a profusion of small white flowers and conspicuous red berries. Growing on a wall with the last named, I noticed in Mr. Mitchinson's garden a rather weather-beaten specimen of *Clematis Jackmanni*. It has been there for several years and continues to produce its handsome flowers throughout the winter—less profusely, it is true, than it would do under more favourable conditions. Several *Dracænas* are almost hardy; during severe winters they are usually killed to the ground, but they generally throw out side shoots from the root during the spring months. Much serious mischief to these very desirable plants may be prevented by carefully collecting the leaves of each close together, securing them in this position by matting; they will then withstand the severest of weathers almost unhurt. Scilly is the home for *Dracænas* and *Cordylines*, although the collection there has suffered much of late years. The number of *Acacias* there is, I believe, considerable. They do not appear to require any special culture, but thrive well in a rather light sandy soil, and in a position sheltered from the winds. As is the case when grown in the greenhouse, unless they are carefully trained and kept within bounds they soon become straggly and ill-shaped.—WILLIAM ROBERTS.

WHAT IS AN AMATEUR?

THIS question appears on pages 349 and 359 of your Journal, and has reference to the method of exhibiting at the late Auricula show. The question should be settled and not shirked, and I think the prizes might be divided better. I suggest the following for consideration and discussion by abler writers than myself. Cannot classes be formed in four sections, as follows:—1, nurserymen; 2, professional gardeners; 3, amateurs; and 4, cottagers?

First, I would allow exhibitors in sections 1 and 2 to show in their respective classes or together; also those in sections 3 and 4. I would allow 3 to show with 2, and 4 with 3, but not in reverse order. A champion class might be formed for the old and successful growers, allowing 1, 2, and 3 section exhibitors to compete.

— The definition of an amateur at present admitted appears to many little short of monstrous, and the manner in which all the gardening journals recognise a gentleman's gardener and a dealer in plants as an amateur is to me very surprising.

A nurseryman is a person who trades in plants.

An amateur is a person who does his own work and does not grow plants for sale.

A professional gardener is a person employed by a gentleman who provides skilled helpers in the management of his garden.

A cottager is a labourer or artisan who does not work as a cultivator in a garden or nursery as a means of livelihood.

The above is quite applicable to all shows of flowers, fruit, and vegetables.—J. E. WAITING, *Grange-over-Sands.*

THE HEALTH EXHIBITION.

THE extensive series of buildings in the Royal Horticultural Society's Gardens, South Kensington, are now crowded with exhibits of much general interest that will undoubtedly attract large numbers of visitors during the season. Horticulturists will find much to admire, but of special interest to them will be the seedsmen's stands, the nurserymen's groups of shrubs and Conifers, while the numerous Promenade, Fruit, and Vegetable Shows to be held by the Royal Horticultural Society during the season will constitute still more important attractions. The grounds have been excellently prepared, the slopes and terraces returfed, the walks newly gravelled, and everything

made as fresh and neat as possible. This part of the Gardens is indeed thoroughly appreciated by the visitors, and is very creditable to Mr. Barron, who has superintended the various improvements effected.

Near the entrance Messrs. Sutton & Sons, Reading, have a prominent position for their large and handsome stand of seeds, grasses, and models of vegetables. The arrangement does not appear to differ in any essential particulars from previous exhibits, but in extent and diversity admirably represent the resources of the firm, whose products have long since obtained a world-wide fame. A short distance from this Messrs. J. Carter & Co., High Holborn, also have a stand which may be termed quite a museum of seeds, fruits, and vegetable products. Much care has been exercised in the preparation and arrangement of these exhibits, which are very interesting. The seeds are placed in small globular glasses, and arranged in groups according to the particular uses of the plants they represent. For instance, there are groups devoted to bee-feeders, textile plants, roots, tubers, &c., Clovers and forage, Grasses, pulse, cereals, oil-yielders, and green vegetables, and besides there is a series of Nuts and berries, and one of prepared products, such as meals of various kinds. Samples of Australian Hops and ensilage, together with specimens of tropical produce, still further increase the interest of these exhibits. Messrs. Webb & Sons of Stourbridge also contribute an excellent stand of vegetable and grass seeds, with models and other appropriate objects, Mr. Wheeler having a stand of a similar nature. A series of accurate models of Indian fruits, lent by the Duchess and Prince of Mantua and Montferrat, forms an interesting exhibit, and includes specimens of the Warty Citron, the Shaddock, Custard Apple, Plantain, Bread Fruit, Mango, Guava, the Cashew Nut, and many others.

The exhibits of preserved fruits and jam constitute another feature of interest, especially as in some cases the mode of preparation is shown. Numerous cases are devoted to representing the chief food products obtained from the vegetable kingdom, showing the parts of the plants employed and the various stages of preparation.

Outside the building are some extensive groups of Rhododendrons, which in many cases are showing abundance of strong buds and giving promise of a handsome display in a few weeks. Messrs. Lane of Berkhamstead contribute very largely, their Rhododendrons being particularly fine, the banks in front of the central annexe and along the east avenue being especially noteworthy. Mr. A. Waterer, Knap Hill, has some tastefully arranged banks of Rhododendrons in the central avenue, also some small Conifers and Hollies. On the east side Messrs. G. Paul & Son, Cheshunt, have a series of pretty beds of Pansies and hardy Azaleas, with a central plant of Rhododendron in each, and two very handsome specimens of *Araucaria imbricata*. A corner bed of Roses, dwarfs and standards, is extremely pleasing, some plants of White Baroness being particularly well flowered; and the miniature rockery, which is well furnished with select alpine plants, is an important portion of Mr. Paul's exhibit. Messrs. Lee & Son, Hammersmith, contribute some small Conifers. Mr. Maurice Young of Milford has a fine bank of Rhododendrons on the west side of the garden, the plants being exceedingly vigorous and well furnished with buds; and Mr. Noble of Bagshot has arranged an extensive and fine representative collection of Conifers and evergreens.

IS OUR CLIMATE DETERIORATING?

A PAMPHLET on the above important subject, prepared by Mr. William Thomson, the Tweed Vineyards, Galashiels, and published by Messrs. Blackwood & Sons, is worthy of perusal by gardeners and cultivators generally, also by meteorologists, as will be apparent by the following copious extracts:—

It would be presumption on my part to give either a negative or affirmative reply to the inquiry, Is our climate deteriorating? What I consider as within the sphere of my ability, and for which my special calling may to some extent qualify me, is to gather up as many facts bearing on the subject as I conveniently can, and let those who may peruse the record of them draw their own conclusions.

Before entering on the present inquiry it may be well to remark, that if we find reason to conclude that a change of climate is going on, there are ample precedents for such change; Fossil flora and fauna give proof of this, and geologists tell us that we have in Britain had a glacial, interglacial, and postglacial climate. These periods saw great changes of climate, and what has been may be again, like causes operating.

From a mass of correspondence I have from gardeners and others who are close observers of the weather and its effects on vegetation, I begin with extracts from letters from Mr. Turnbull, who has been gardener at Bothwell Castle, near Glasgow, since 1828. Mr. Turnbull is well known as a very shrewd observant man, and he has kept notes of the weather for more than fifty years. I was under his tuition from 1832 till 1837. During these five years he never failed to have fine crops of Peaches, Nectarines, and Apricots on the open walls. He had also great crops of Green Gage Plums and splendid Ribston Pippin Apples that kept till April of a golden colour and quite firm. It will be observed that the last fine crop of Peaches he had was in 1870, and the Apricot trees have been twice destroyed by the weather. At the same time Mr. Turnbull does not believe that the weather is deteriorating permanently. He expects that the seasons will yet become as genial as they used to be.

He writes: "I am afraid you will find the deterioration of our climate rather a ticklish subject, for we have had a very variable climate for a hundred years. 1782 was a very severe winter. The winters of 1813 and 1814 were also very severe. 1836, you will remember, was a very late harvest—much corn in Lanarkshire and elsewhere was covered by a foot of snow before it was cut, and some never cut at all. 1838 was Murphy's season, and with us the temperature fell to $3\frac{1}{2}^{\circ}$ below zero. 1839 was a very late spring—we had a fall of snow on the 14th of May, and a severe frost on the 15th, which destroyed all our fruit. On the 24th December, 1860, the temperature fell to 11° below zero, and killed all our Laurels and many other shrubs. In 1881 we had the thermometer six times below zero. The wood of our Peach trees not being well ripened, that and the following year nearly killed the whole of them. We had good crops of Peaches in 1870. The young trees I planted after the others were killed are looking well; and if the seasons

take a favourable turn they may be good again, and so may agricultural crops."

This evidence, given by Mr. Turnbull, seems to prove that for some time back there has been a swing of the pendulum in the direction of less genial weather; and it is from this cause more than any other that agriculture is suffering at this time. Let us hope that the swing in an opposite direction may soon commence.

Mr. Kinghorn of Sheen Nursery, Richmond, in reply to my inquiry, writes: "With regard to our climate—when I came to Orleans House, Twickenham, in 1837, and for ten years afterwards, I never covered the fruit trees on the walls when in bloom, and always had good crops; but after that date I was obliged to take to covering them. Till 1847 we invariably had good crops of Figs both on wall trees and standards, the latter bearing abundantly. Vines also bore well on the walls, and ripened their fruit nicely. In 1847 the mildew attacked them (brought about by cold and damp), and they were no longer worth the attention they required. I have observed that for the last twenty-five or thirty years Peach, Nectarine, and Apricot trees do not make the growths they used to do, neither in stem nor branches. Certainly we have had more severe winters since I came to England than they could have had before for many years, judging from the large Evergreen Oaks, Arbutus, Laurels, and Cedars that have been killed, as well as great old Banksian Roses and Myrtles—the latter, to my knowledge, 23 feet high, with great thick stems—none of which seem likely to be replaced, unless we have a change of climate for the better, of which at present there seems little prospect."

Mr. Thom, who has been for many years gardener at Newton Don, near Kelso, Roxburghshire, states that no kinds of fruits are to be compared with what we grew forty years ago, and he attributes the change to the want of sun in summer and the severe winters.

Mr. Brown, gardener at Abercrairie, near Crieff, writes: "Referring to your inquiries about the weather, and the influence of climatic change on our fruits, looking back for thirty-five years, it is a fact to my mind that, though we have improved much in indoor culture of fruit, we have fallen back in outdoor. I have been a visitor to the Carse of Gowrie for the last forty years, and the Apples, as seen there now, are not worth using, as compared with what they were in my young days. Here, at Abercrairie, I am gradually, even on the south walls, doing away with all the fine Pears, and putting on the common hardy sorts. Ribston Apples, such as I knew in my youth, are not now to be had. I attribute this chiefly to climatic change, and partly want of attention to outdoor fruit."

Mr. Lindsay of the Edinburgh Botanic Gardens, writes:—"During my connection with the garden, some twenty-five years, the plants on the walls, with few exceptions, are the same, and I should say most of them were planted by Mr. William M'Nab. The following are a few which have disappeared from the walls, even during my recollection—viz., *Paulownia imperialis*, *Bignonia radicans*, *Acacia dealbata*, *Eucalyptus*, and *Escallonia*. In other parts of the garden—Arbutus, all old plants; *Quercus suber*; *Alaternus*, many varieties; *Phyllyrea*, also many varieties; *Robinia serrulata*, &c., &c. Some of these are being replaced with young plants; but it is disheartening to find them making such slow progress. A few plants still survive that are considered tender, and that have been unprotected for fifty years, such as the Tea Plant, *Chamærops humilis*, various New Zealand Veronicas and shrubs, which only proves that they are harder than was generally supposed."

All who read Mr. Lindsay's letter will, I think, admit that it is a very interesting one; and at least it goes far to show that the swing of the pendulum of the weather is in the direction of deterioration in the current century.

Mr. Webster of Gordon Castle is "inclined to fancy our springs are colder and more uncertain and precarious, our autumns more frequently wet, and summer heat shorter than in bygone years."

Mr. Barron, Superintendent of the Royal Horticultural Society's Gardens at Chiswick, writes: "I do not think that our climate has deteriorated. I may not be observant enough, 'tis true, and am aware there have been a number of cold sunless seasons lately. 1883 was an exception in this quarter, being one of the mildest, the month of July excepted. The present autumn has been one of the clearest and mildest ever experienced."

In a second letter Mr. Barron writes: "I quite agree with you that we have been passing through a period remarkably unfavourable for fruit cultivation. This I attribute partly to cold wet weather in May, and to cold wet autumns, which has prevented the proper maturation of the wood."

Mr. Barron, however, thinks this unfavourable weather is only temporary. Mr. Rust, gardener, Eridge Castle, Tunbridge, is disposed to think the springs more backward and ungenial than they used to be. Many others express similar opinions, and not one of the many gave it as his opinion that seasons for years back have been as suitable for vegetation as they were at one time.

The evidence of Mr. Pettigrew of Cardiff Castle, on growing Vines in the open air, is also adduced, and Mr. Pettigrew concludes: "The seasons must alter considerably, or the Vineyard experiment at Castle Coch will turn out a complete failure."

From the gardener at Torloisk, in the Island of Mull, I have the following replies to my inquiries: "The Hydrangeas still grow out of doors here during summer and winter, but do not flower well. The wood is never properly ripened in autumn, and the damp and frost together cut them down."

In my knowledge of these plants, more than fifty years ago, they were great bushes, covered every summer with fine masses of bloom. With regard to Plums and Pears, he replies: "There are no Magnum Bonum Plums nor Jargonelle Pears here now; and I am certain they would not ripen. Even Apples do little or no good here, except on walls."

I have given a fair sample of this class of evidence, and will now make some extracts from a scientific writer in a Swedish journal, headed: "Why is the Climate of Europe Growing Colder?" He replies: "Because that for some years the floating ice has extended a great way towards the south—thus between Greenland and the Arctic Sea colossal masses of ice have accumulated on European coasts. Navigators now frequently find ice in latitudes where it never before was found in summer months; and the cold reigning upon the Scandinavian peninsula last summer was the result of the immense masses of ice floating in the region where the Gulf stream bends

towards our coast. This is a repetition of the observations made in the summer of 1865. The unaccountable vicinity of the masses of ice has rendered the climate of Iceland so cold that corn no longer ripens there, and the Icelanders are in such fear of a coming famine and ice climate that they are beginning rapidly to form for themselves a new home in North America."—(Copied from a translation in the "Ladies' Journal.")

I now submit such evidence as I have been able to collect from an earlier date and wider field.

VINEYARDS IN ENGLAND.

In "Pomona Fruit Garden, Illustrated," by Batty Langley of Twickenham, 1729, he describes various methods of growing Grapes for making wine in open vineyards, each Vine producing from ten to twelve bunches of Grapes, and adds: "If any doubt or dispute the truth hereof let them but go and see the Vines now growing in the garden of Mr. Warner at Rotherhithe, which, by his judicious management after the manner before described, annually produce great quantities of Burgundy, and, if I mistake not, claret Grapes also, with which he makes cheerful nectar for the accommodation of his friends."

Mr. Langley then gives a dissertation on the growth of Grapes against walls in England. He had a high opinion of one he calls "The July Grape," because it ripened in that month. The Royal Muscadine did not ripen till the 15th of August. Figs gave two crops a year—one ripe about July 10th, the other in September.

I fear there is no Grape in cultivation at present that will ripen in July in the climate of London. The Royal Muscadine is a well-known Grape; but I am disposed to think that in no part of Britain will it ripen on the open wall as early as August 15th, which it appears to have done 150 years ago.

I have a very old book, which was printed in 1631. It is a republication, by a "Captain Garvase Markham," of a much older book called "The Whole Art of Husbandry." In it the Grape is treated of as a commonly cultivated fruit in England.

Having often visited a very sheltered spot in Hatfield Park, Herts, known by the name of "The Vineyard," sheltered on one side by a grand old Yew hedge that appeared to be three hundred years old, I thought it likely that at some date it must have been planted with Vines after the style of those of France and Germany.

I recently asked the proprietor, the Marquis of Salisbury, if he could give me any information regarding it, and he most courteously directed his Secretary to send me the following communication:—

"Hatfield Park, January 2, 1884.

"SIR,—I am directed by the Marquis of Salisbury to acknowledge receipt of your letter of the 29th December, and, in reply, to send you the enclosed notes with regard to the Vineyard at Hatfield.

"I am, yours, &c., H. T. GURTON."

"The Vines at the vineyards at Hatfield were planted in 1610–11. As the vineyard was 5 acres in extent, and 30,000 Vines were planted, it may be concluded that they were standards. The Vines were a present from the wife of the French ambassador to Sir Robert Cecil.

"It is probable that this was one of the latest vineyards planted in England. There is no record of the time when it was abandoned. Vineyards in England are mentioned as early as A.D. 280, and there are thirty-eight entries of vineries in the Doomsday Book (compiled 850 years ago). Camden says, in his 'Britannica': 'It may seem to be the slothfulness of the people more than the indisposition of the air that this nation yieldeth not wine at this day.' The vineyards probably declined gradually with the growth of commerce, which enabled better wine to be got from France than could be produced at home. (The overthrow of the monasteries gave the finishing blow to home production of wine.)

"Parkinson, writing of vineyards in 1627, says: 'The former vineyards in England have long since been destroyed, and the knowledge how to order a vineyard has entirely perished with them.'

"Austin, writing in 1663, gives as a reason why it is fruitless labour to strive in these days to make a good vineyard in England—'That the years are not so hot in England as formerly.'

It will be remarked that Austin blames the climate for the abandonment of open-air culture of the Vine for wine-making.

SEVERE WINTERS.

In an inquiry of this sort the severity of recent winters must be taken into account, and I think it is pretty certain that no such frost, in its fatal effects on vegetation, as that of the 4th December, 1879, had occurred for 300 years. The grounds upon which I make this statement are—first, that old Yew trees that had stood the frosts of more than 300 years succumbed at that time, as at Floors Castle and elsewhere; and, second, that I looked over the "Chronicles of Fortingal," being extracts made from the "Black Book of Taymouth," by Cosmo Innes, where special reference is made to only two severe winters during a like period. In the one case frost and snow began on the 30th November, 1554, and continued till 17th January, 1555. The next notably severe winter began on January 15th, 1572, and lasted till March 22nd.

These, by the reference made to their effects, seem to have been on a par with 1879.

THE WEATHER ABROAD.

Recently the climate has been peculiarly erratic. For instance, in Florida, on the shores of the Gulf of Mexico, which supplies the Gulf stream with its tepid water, Orange trees that had stood for one hundred years have been killed by frost last winter, and in others of the Southern States of North America railways have been blocked where snow was hardly ever seen before.

The State of New York, twenty years ago, produced for exportation 1,750,000 barrels of that finest of all Apples, the Newton Pippin, in the highest condition of excellence; now it produces only 250,000 barrels, and they are small and very inferior in quality. There is still a great quantity of an Apple called the Newton Pippin exported. It is, however, a very inferior Apple compared with the true one. Unfavourable change in the climate is the assigned cause of this falling-off in the supply of the true Newton Pippin.

An extensive fruit-importer in Edinburgh recently showed me a letter from his correspondent in Spain, begging to be released from a contract to

supply 5000 boxes of bitter Oranges, on the ground that nearly all the fruit in the district of Seville had been destroyed by frost, which was, he said, an unprecedented occurrence.

SUMMARY.

It seems to the writer that the weather has got curiously mixed of late. Such a succession of severe storms of wind in Britain as no living person can remember; this accompanied by very mild temperatures, while frost and snow are stopping the trains in some of the Southern States of America where snow is seldom seen; sunsets of the most gorgeous description, and earthquakes on the most gigantic scale—all pointing to some disturbance within, at least, the atmosphere of our planet. Whether this is the result of stellar influence or not some of our scientific men may be able to determine. In the meantime the ungenial weather we have had for some years has been in large measure the cause of the depression of the great interest of agriculture, and through it all other interests have suffered, and will suffer still more if the average temperature sinks but a degree lower than it has been of late years. The warm nights of my boyhood and early life, where are they now? Do ladies wear thin muslin dresses now, as their mothers wore nearly all the summer? "As hardy as a Whin bush" used to be an aphorism. It can no longer be given as such, for the Whin has been killed to the surface of the snow or soil almost annually of late years.

I am indebted to Mr. Buchan for notes, of which the following is a digest:—

The mean temperatures of the months of May, June, and July for forty years—from 1840 to 1880 inclusive—show that the twenty years from 1840 to 1860 were warmer than the twenty from 1860 to 1880 by 40.2° on the three months; and supposing the same ratio to hold good over the year, it would give 160.8° on the twenty years. This is not much when divided over twenty years; still it is on the adverse side, and we have but a small margin we can afford to lose in these latitudes.

MEDINILLA CURTISII.

FOR compactness of habit and floriferousness this charming little plant is not surpassed by any of its relatives, and these characters alone would be sufficient to render it worthy of attention. Beyond those recommendations, however, it possesses such a simple and pleasing beauty that it will certainly rank high amongst favourite flowering stove plants. Again, too, the flowers are produced at a season when they seem to be doubly welcome—namely, the autumn, October and November, and lasting for several weeks, their value in a stove cannot be too highly rated. Many very distinct handsome plants are contained in the Melastomad family; but, imposing as some of these are, *Medinilla Curtisii* is likely to become one of the most useful garden plants of those yet introduced.

It is a native of Sumatra, and was introduced thence by Mr. Curtis for Messrs. Veitch & Sons a short time since, plants being exhibited at Kensington on October 9th, 1883, when a first-class certificate was awarded for it. The habit is bushy, as shown in the woodcut (fig. 90) kindly lent us by Messrs. Veitch & Sons. The leaves are oblong or elliptical, bright green, with midribs and veins coloured of a reddish tint. The flowers are borne in terminal and axillary clusters, the petals are creamy white, the sepals similar, and the dense central tuft of stamens purple—a pretty contrast. It is easily grown, needing only a moderately light open compost of peat and loam, and the temperature of an ordinary plant stove.

SPRING GARDENING AT BELVOIR.

PROBABLY no garden establishment in these times can vie with Belvoir in spring gardening. Those who only know Belvoir by name can form no idea either of the extent and exquisite arrangements which are there to be seen. Spring gardening there is quite distinct from that generally bearing the name; we find no formality, no geometrical design with flattened surface and unique precision, but, on the contrary, a wealth of floral beauty.

It was a glorious April morning when I started for Belvoir, where I soon found the enthusiastic gardener, Mr. Ingram, who never tires discussing spring gardening with others of like tastes. On entering the Castle grounds we ascend a winding path and the terrace garden is reached. Ahead the visitors can behold a picturesque landscape extending for many miles, and the floral beauties which surround him on all sides. Here my guide drew my attention to the Castle walls above us on our right, bedecked with Magnolias and Forsythia suspensa, the latter covered with bloom. Passing along we enter the Castle garden, in which, considering the few plants employed, the effect produced is marvellous. Conspicuous as a main feature is *Saxifraga ligulata*, one of the Megasea group or large-leaved Saxifragas, in grand masses, and spikes of its rosy-red blooms 15 inches high, a telling plant, and in front of this is a *Cardamine grandiflora*; the white is good and remarkably early, and plants having these qualities are by no means common in early spring. *Myosotis dissitiflora*, which holds its own against all comers, and the intense blue of the Siberian Squill, an exceptionally dwarf form of *Arabis albida*, together with overhanging masses of *Aubrietia græca grandiflora* were very handsome. Other beds in this garden were filled with Violet Marie Louise, and bearing hundreds of flowers. Here are also to be seen *Anemone coronaria*, some remarkably fine early Cowslips,

which Mr. Ingram recognised as *Primula macrocalyx*; these produce excellent effect, and are the outcome of continually selecting the earliest and best. The most noteworthy of other plants used in this garden are *Doronicum austriacum*, *Primula auriculæflora*, with rich crimson maroon flowers, Hyacinths and Tulips, good clumps of *Helleborus orientalis*, *Narcissus* in variety, and many more. Almost unique in effect are mounds of *Saxifraga muscoides atropurpurea*, which was just bursting into bloom, nestling in a carpet of the downy leaves of *Antennaria tomentosa*. One large bed had *Polyanthus* and red Hyacinths as a centre, next a band of *Euonymus*, then *Primula auriculæflora*, and double crimson Daisies. Some handsome tufts of *Hepatica angulosa*, though its season of flowering had passed, are worthy of special note, as being probably the most attractive and largest flowered species, and at the same time the earliest.

We turned to leave this delightful spot with considerable reluctance. Not the least worthy of note are the grassy slopes and rising banks

We next ascended a winding path, rugged as the mountain side, and in advancing from ledge to ledge something new was constantly coming into sight. On all sides are hardy Heaths grouped in small colonies, *Helianthemums*, the purple form of *Corydalis solida*, *Cardamine*, *Pulmonaria*, *Doronicum*, *Gentiana tinctoria* for later bloom, banks are wild with the Wood Anemone (*A. nemorosa*), and Primroses; while the spring Navewort (*Omphalodes verna*) and its white variety are in the greatest profusion. Few know the splendour of these charming plants, and what can vie with the intensity of the Gentian blue of the typical species?

Descending a grassy slope we noticed a powerful fragrance produced from a fine bush of *Azara microphylla*. Next we saw the ever-flowering *Primula obconica*, which promises to be among the foremost of the genus, *P. rosea* and the striped Squill (*Puschkinia scilloides*), the colouring somewhat fainter than usual, consequent on the age of the flowers; this is still a rare and charming plant. Then we saw the lovely Anemone *Robinsoniana* and *A. blanda*. Here also was *Narcissus minimus*

FIG. 90.—MEDINILLA CURTISI.

which are viewed from this elevated position, and below in the valley are to be seen groups of *Bambusa Metake*, probably the hardiest of all evergreen Bamboos; *Azalea mollis* in great variety, *Spiræa Thunbergii*, *Berberis Darwini*, all in perfection; and crowning one of these slopes the crimson trusses of *Rhododendron Jacksoni*. On one of these banks Mr. Ingram has already established many choice plants; on the one in question *Narcissi* predominate, having for companions *Crocuses*, *Snowdrops*, *Scillas*, *Anemone apennina*, the lovely *Chionodoxa*, and others to succeed, with sheets of *Myosotis dissitiflora* at every turn. Charming everywhere and flowering profusely was the Snow Glory, though few seem at present to realise its value. Happily, however, Mr. Ingram is not of that number, for already has he established it on semi-wild banks with charming effect, and where he intends it to seed at will, the result of which in a few years will be worth a journey from the remotest parts of England to behold. No plant of recent introduction is so well adapted for naturalising as this. It cannot be had in perfection in pots, for which purpose it has been so strongly recommended; it must have freedom, and if allowed to seed in the border or a sheltered position on the rock will soon surpass any other spring bulbous plants at present in cultivation.

just passing out of flower, and many others too numerous to mention. Close by, in a newly established peaty bed, were *Cypripediums* springing up, *Trilliums*, *Gentianas*, and a lovely show of the golden flowers of *Anemone ranunculoides*; and on the grass were groups of Ferns, *Spiræas*, and *Saxifraga peltata*, all of which will play their parts through the coming summer months.

There is also a rich collection of plants in Mr. Ingram's reserve garden, which cannot be fully described. *Narcissi* is in abundance, including the rare *minimus*, *Chionodoxa* by hundreds, *Anemone coronaria* (single and double) with their fiery heads, *A. fulgens* in plenty, and likewise *A. Robinsoniana*, *A. blanda*, and *A. apennina*. Of *A. blanda* Mr. Ingram annually raises many seedlings, some of increased size and vigour. Among many others worthy of note may be mentioned *Tropæolum polyphyllum*, not content with its allotted space in the bed is springing up abundantly in the walks. It is in this garden that every fresh arrival is thoroughly tested before it becomes entitled to a place in the spring garden.

Finally, what a boon is all this to the outer world, who, by the gracious permission of the noble owner of Belvoir, are allowed to inspect such a paradise of flowers. They come by hundreds, a fact alone which

speaks of the high appreciation in which it is regarded, affording satisfaction to the untiring energies of the gardener, Mr. Ingram, who is ever ready to welcome and instruct all lovers of hardy plants.—E. JENKINS.

ROSES IN THE AZORES.

THE accompanying Rose pods are from gardens in the islands of St. Michael's, Terceira, and Fayal in the Azores. Out of a large collection made by me during the past winter (the seeds without pods weighing over half a pound) I have selected these for their size, in order to give some idea of the strength of the plants which have produced them.

Some are of sorts I found unnamed, the others consisting chiefly of Teas Cloth of Gold, Madame Willermoz, Safrano, and Souvenir d'un Ami. On my way home I had an opportunity of showing the entire collection to a number of German gentlemen (principally planters) returning from Brazil, and they informed me that they had not seen such large Rose pods in Brazil. One or two Scotch gardeners who have seen them have also been surprised at the size of the pods. As some of them have now been collected two and three months they have of course shrunk considerably.

It will amuse your readers to know that I have constantly been asked whether these Rose pods were not small Apples.—ALEXANDER HILL GRAY, *East Ferry, Dunkeld.*

[The pods are very fine indeed, and we have little doubt are those of the Japanese Rose, *Rosa rugosa*, a spray of which was figured on page 293, vol. iii., third series, of the Journal, the issue of September 29th, 1881.]

ROYAL HORTICULTURAL SOCIETY.

MAY 13TH.

THOUGH the exhibits were less numerous than at some previous meetings this season, a beautiful display was provided in the conservatory, the Roses forming an exhibition alone. Calceolarias and hardy flowers were also in good numbers, the rare plants keeping the Floral Committee fully employed for a considerable time.

FRUIT COMMITTEE.—J. E. Lane, Esq., in the chair. Present—Messrs. J. Ellam, Phillip Crowley, G. T. Miles, S. Lyon, J. Burnett, G. Bunyard, C. Silverlock, A. W. Sutton, W. Paul, G. M. Breese, F. Rutland, J. Lee, H. J. Veitch, J. C. Mundell, and G. Goldsmith. The principal exhibit, and an extremely meritorious one, was that from Mr. Coyst, gardener to C. H. Wood, Esq., Newbold Revel, Rugby, which consisted of six handsome Melons, beautifully netted, of even but moderate size, flesh deep, and flavour fairly good for such early fruits. The variety is a cross between Conqueror of Europe and Scarlet Gem, and the cultural commendation awarded was well deserved. Mr. Ham, The Gardens, Mountains, Hildenborough, sent samples of a fine Broccoli with solid white hearts. It was a selection from Leamington, which was sown with Suttons' Late Queen and Cattell's Eclipse in the middle of June, 1883, and came into use at the same time as Late Queen. Mr. Ham finds Cattell's Eclipse the latest of the three, with fine solid hearts. A vote of thanks was accorded to Mr. W. Divers, The Gardens, Wierton House, Maidstone, for a dish of Ashtop Fluke Potatoes and a collection of Rhubarb of good colour. Mr. B. S. Williams, Upper Holloway, showed fruits of an early Melon named Basing Park Hybrid, which were of moderate size, globular in form, with the flesh fairly deep and of a rich yellow colour. Mr. C. Turner sent a dish of well-kept Winter Pearmain Apples, and Messrs. Lane & Son, Great Berkhamstead, showed two dishes of Apples—Galloway Seedling and Lane's Prince Albert, the latter being especially good. A specimen contrivance for assisting in bunching Asparagus was shown by Mr. H. Eldridge, Chesterfield Park Gardens, Saffron Waldron. It consisted of two flat pieces of wood secured together by hinges, the shorter one at right angles with the other. In the lower longer piece several holes are bored, in which pegs are placed to regulate the size of the bundle, the end piece keeping the heads all even, and the bundle is then readily tied.

FLORAL COMMITTEE.—Section A.—John Fraser, Esq., in the chair. Present: Rev. G. Henslow, Dr. Maxwell T. Masters, and Messrs. E. Hill, J. O'Brien, J. Hudson, J. Woodbridge, H. Herbst, J. Laing, H. Ebbage, and T. Moore. Section B.—Shirley Hibberd, Esq., in the chair. Present: Messrs. H. Bennett, W. Bealby, G. Duffield, D. C. Lathbury, H. Cannell, W. B. Kellock, and H. Turner.

A group of Roses such as that contributed by Messrs. W. Paul & Son, Waltham Cross, at this meeting is very rarely seen in May, and the gold medal adjudged for it by the Council was only a fitting recognition of its merit. About seventy plants were staged, varying in height from 3 to 5 feet, and in pots from 10 to 18 inches in diameter, while twenty large exhibition boxes of cut blooms placed along the front served to complete a group which for freshness, colour, and fragrance could have scarcely been surpassed. The plants were in extremely vigorous health, the foliage rich green, and well developed, the blooms mostly of good substance, but in a few instances, owing, no doubt, to the sudden heat of the past few days, they were a trifle too full; however, there was abundance of fresh bright buds and half-developed blooms. Numerous varieties were represented, and amongst them were some fine examples of Ulrich Brunner fils, with large rich rosy crimson blooms; Queen of Queens, bright and beautiful; Madame Lelievre Delaplace, a comparatively new variety with broad petals of a rich rose tint; Charles Lefebvre, extremely handsome, unsurpassed in colour; Marguerite de St. Romans, a globular bloom with shell-like petals, pale pink, of good substance; Crown Prince, a pretty Rose, especially in the bud, deep crimson, occasionally with a scarlet tinge; Mdle. Emile Fontaine, bright crimson scarlet, free; Etienne Levet, Masterpiece, and Madame Montels were also notable. A seedling Hybrid Perpetual of dwarf habit, and said to be valuable for bedding, was included in the group. The blooms are not of first-rate form, but of a rather pleasing rose tint, and are produced in great numbers. The Noisettes, Solfaterre and Rêve d'Or, were fine, the general favourite, La France, being represented by several plants bearing from eighteen to twenty-four large blooms. The plants were tastefully arranged

in the western portion of the conservatory, where they occupied considerable space.

Next in importance to the Roses were the Calceolarias, of which two beautiful collections were staged, and for each a silver Banksian medal was awarded. By far the most tastefully arranged was that from Mr. May, Dyson's Lane, Edmonton, in which a suitable proportion of healthy Adiantums were employed, together with a margin of wonderfully strong *Isolepis gracilis*. These formed a pleasing foil to the richly coloured flowers of the Calceolarias, and showed them to much better advantage in consequence. The plants were dwarf and compact, bearing fine heads of diversely coloured blooms, self or spotted, in great variety. It is evidently a useful strain, and well adapted for market. The other group was from Mr. H. B. Smith, Ealing, whose skill as a grower of such plants is well known. They were all in good health and admirably flowered, but their beauty as a group was much lessened by the absence of foliage plants. For richness of colour this strain is admirable, and the flowers also are well formed, full, and neat. Much improvement has been effected amongst the Calceolarias grown for market of recent years; they are now much more compact and dwarf than formerly, and though the heads of flowers are not quite so large, the first-named characters are of the most importance.

Hardy flowers constituted another attraction of equal interest to the preceding, and again were silver medals awarded for two representative collections. Mr. T. S. Ware, Tottenham, had a very choice and beautiful selection, prominent amongst which were several varieties of the handsome Tree Pæony, *Pæonia Moutan*, the large imposing flowers being of several shades of rose or crimson, differing but slightly, though all were beautiful. *Erigeron aurantiacum*, with large dark orange flower heads, was especially noteworthy; other good plants being *Linum flavum*, with abundant pale yellow flowers of good size for a hardy Flax; the Irish Butterwort (*Pinguicula grandiflora*), a charming little free plant with violet purple flowers; the creeping *Lithospermum prostratum* with its purplish blue flowers, so pretty on a rockery; the scarlet dwarf Pentstemon-like plant *Ourisia coccinea*; the very distinct shrub *Eurybia Gunni*, of which the white flower heads are so suggestive of the shrubby autumn-flowering Asters; several *Fritillarias*, *F. pyrenaica* being especially notable for its recurved petals; a host of charming Daffodils, still fresh and beautiful; and a pot of the pretty *Houstonia cærulea alba*. The collection of choice named Tulips (*bybloemens*) must not be omitted, for they were greatly admired, and formed a very pretty addition to the group. Messrs. Barr & Son, King Street, Covent Garden, principally exhibited Daffodils, and it was surprising what a number of varieties were still in bloom. The N. poeticus forms, such as *ornatus* and *poetarum*, were unsurpassed in their section. N. bicolor and its variety *primulinus* were good. *Abscissus*, *Nelsoni*, the double *Codlins and Cream*, *Barri conspicuus*, *incomparabilis expansus*, and many others were very attractive. Of the general collection, Anemones, Irises, Tulips, and Scillas were the chief features, several pretty varieties being included, such as the white, pink, and blue forms of *Scilla nutans*, and the Emperor and Empress varieties of *Scilla campanulata*, which are distinguished from the type by their larger flowers.

The Japanese Maples were much admired, and considering the elegance of these plants and their hardiness in most parts of England, even as far north as York, it is surprising that they do not become more popular. Messrs. J. Veitch & Sons, Chelsea, had a collection of distinct and graceful varieties, several of which were certificated. The best were *Acer polymorphum septemlobum elegans purpureum* (an appalling name), which has neatly divided purple leaves; *ribesifolium* with green close leaves; *laciniatum*, leaves deeply and finely cut; *atropurpureum*, dark purplish red, and *japonicum aureum*, pale golden yellow. With these also were grown the bright rosy salmon *Azalea rosæflora*, and a white variegated Dogwood named *Cornus brachypoda variegata*. The New Plant and Bulb Company, Colchester, also had a group of these Maples under their Japanese names. Some of the varieties were extremely pretty, and as a curiosity may be noted one plant upon which had been grafted no less than eight distinct varieties. For these groups bronze medals were awarded.

Alpine Auriculas, richly coloured and extremely fragrant, formed a pleasing group from Mr. C. Turner of Slough; and from about fifty, many of which were seedlings, the following were selected as the most distinct:—Mrs. Ball, crimson shaded, gold centre; Arthur Potts, violet purple shaded, cream centre; Ellen Terry, rich purple shaded, white centre; Queen Victoria, light crimson shaded, cream centre; Model, bright crimson shaded, cream centre; and Homer, crimson scarlet shaded, gold centre, free and very effective. A box of a dozen fine Maréchal Niel Rose blooms and two boxes of Carnation blooms were also contributed by Mr. C. Turner. Of the latter, the best varieties were Mrs. Maclaren, certificated; Mrs. Llewelyn, pink; Ruby, purple, very large; Rufus, scarlet; and Negro, maroon. All selfs except the first.

New or notable plants were also contributed by the following exhibitors, to whom votes of thanks were accorded:—Mr. B. S. Williams had several Orchids and other plants, such as *Cattleya Mossiæ magnifica* with large grandly coloured flowers; *Odontoglossum Alexandræ splendens*, a magnificent variety; *Masdevallia Veitchi grandiflora* with flowers 6 inches long and 2 in diameter; *Selaginella viridangula*, a tall-growing form with much-divided leaflets; *Osmunda javanica*, *Aralia reginæ*, and *Gloneria jasminiflora*, the latter bearing a number of its white flowers. From Messrs. Veitch came a fine plant of *Boronia elatior* profusely flowered, and a plant of *Gloxinia Purity* with pure white flowers. By the New Plant and Bulb Company a fine variety of *Cattleya Mendellii* named *Wallacei* was shown, the sepals and petals blush-tinted, the lip half crimson and white. T. O. Cunningham Graham, Esq., Dunlop House, Stewarston, Ayr, sent some fine spikes of *Vanda suavis*, variously coloured. Mr. Robbins, gardener to J. Vanner, Esq., Camden Wood, Chislehurst, showed a beautiful variety of *Odontoglossum citrosum* named *roseum*, which has large white sepals and petals and a bright purple lip. Sir Trevor Laurence, Bart., Burford Lodge, contributed plants of the profuse and attractive *Masdevallia rosea*, and an extraordinarily fine spathe of *Anthurium ferrierense* 6 inches broad and 7 inches long, the spadix being of similar length; the colour was a fine deep red. Messrs. Lucombe & Pince, Exeter, sent spathes of *Anthurium Schertzerianum giganteum*, a variety distinguished by its great size and deep colour. Mr. C. Noble, Bagshot, had some double and single Clematis flowers; Messrs. Laing & Co., Forest

Hill, some handsome tuberous Begonias; Mr. R. Phillips, The Gardens, The Deodars, Meopham, a collection of well-grown Gloxinias; and Mr. Gray Cragg, Crouch End Road, plants of a double Wallflower named Souvenir of the Duke of Albany. Mr. R. Dean, Ealing, showed specimens of the charming *Iberis gibraltarica hybrida* from the open ground, the lilac or white flowers being of considerable size and borne in dense heads. From the Society's garden at Chiswick pretty groups of Gloxinias, Ferns, Cape Pelargoniums, and a specimen of the strong-growing *Todea africana* were also contributed.

First class certificates were awarded for the following plants:—

Carnation Mrs. Maclaren (Turner).—A crimson bizarre with large substantial blooms; well formed and even.

Phlox setacea Vivid (Ware).—One of the dwarf Phloxes, very free with bright pink flowers having a deep red centre. An excellent variety, one of the best coloured forms.

Calochortus Benthani (Ware).—Very distinct and pretty, and well worth a higher award than the second-class certificate granted. The flowers are $1\frac{1}{2}$ inch across; the sepals tapering petals ovate, bright yellow, brown at the base, having on the upper surface a number of large hair-like appendages.

Mimulus moschatus Cloth of Gold (Dean).—A dwarf pretty flowering variety with large yellow blooms.

Odontoglossum Alexandræ delliense (Baron Schröder).—Chiefly remarkable for the dark chocolate prominent spots and the purplish tinge, as the flowers are of moderate size, though well formed.

Odontoglossum Alexandræ Ballantynei (Baron Schröder).—A handsome variety; flower large, petals and sepals broad, white, with a dark central blotch of chocolate; lip large and beautifully formed.

Brassia antherites (Williams).—A remarkable Orchid. The flowers are 7 inches in diameter from tip to tip of the sepals. Sepals and petals narrow, one-eighth of an inch broad, tapering, yellow, brownish black at the base. Petals $1\frac{1}{2}$ inch long. The lip is triangular, yellow, barred with brown. The spike was strong, over 2 feet long.

Saccolabium curvifolium superbum (W. Lee, Esq., Downside).—A richly coloured variety, the spike 6 inches long, and the flower of a clear reddish scarlet hue.

Cattleya Mendelli selbornensis (W. Lee, Esq.).—Very beautiful, sepals and petals pale purplish crimson, the latter very broad. The lip is delicately fringed, rich crimson at the point, gold and white in the throat.

Masdevalli Chelsoni (Sir Trevor Lawrence, Bart.).—A neat, freely flowering Orchid, the flowers somewhat like a small *M. Veitchii*, red scarlet, with a yellow tinge, a peculiar colour.

Phalænopsis sumatrana purpurea (Sir Trevor Lawrence).—Flowers 2 inches in diameter, white with bars of brown; the lip is a warm crimson purple. Very distinct and pretty.

Cypripedium grande (Sir Trevor Lawrence).—A wonderfully strong plant, which, owing to its fresh green leaves, is handsome even when out of flower. It had two spikes with three to four flowers each, the petals 9 inches long, narrow, and twisted, of a rosy tint. The sepals are large, of a very pale brownish colour with darker veins. The lip is greenish, very pale, with spots on the margin.

Asplenium horridum (Williams).—A bold and effective Fern, with fronds 18 inches to 2 feet long, pinnate, with dark brown or black stipes; pinnæ 4 to 5 inches long with rounded segments.

Zonal Pelargonium Belle Nauceinne (Laing).—A double salmon-coloured variety, bearing a remarkably large dense truss of full flowers.

Acer japonicum aureum (Veitch).—Very distinct; the leaf is 3 to 4 inches across, and has eight or nine short lobes neatly serrated.

Acer polymorphum septemlobum elegans purpureum (Veitch).—A dark-coloured form, the leaves having 5 to 7 deep, narrow serrated lobes.

Variegated Sycamore (C. Kershaw, Brighouse).—The leaves of this were of a reddish tinge, but as they seemed to be but half expanded, it was in the opinion of many persons scarcely worthy of a certificate.

SCIENTIFIC COMMITTEE.—Dr. M. T. Masters in the chair.

Aloe ferox attacked by Death-watch Beetle (*Anobium striatum*).—Mr. Maclachlan showed a piece of stem from Kew. The beetle apparently confined itself to the exterior dead wood, and was therefore presumably not injuring the living plant within. Kerosene was recommended as the best thing to apply.

Larvæ of Lepidoptera.—He also showed some very remarkable "cases," some exactly resembling a *Helix* or *Cyclostoma elegans*, others like that of the Caddis worm. They were made by species of *Psychidæ*, and came from Mpwapwa, about one hundred miles from Zanzibar.

Potatoes Growing in the Dark.—Mr. Houston exhibited some Potatoes in which the sprouts were short, and producing a dense mass of coral-like branches instead of developing into elongated shoots. It was probably due to pressure under confinement.

Canker in Service Tree.—Mr. Grote exhibited a bough of *Pyrus Sorbus* or *P. domestica* sent by Mr. Frere of Roydon Hall, Norfolk. As the cause was not apparent Mr. Grote will acquire more information and report upon it.

Plants Exhibited.—Mr. Loder showed the following:—A fine spike of *Fritillaria Thomsoni* grown in a cold pit; *Primula dolomitica*, *Muscari latifolium*, and *M. atlanticum* (?), *Scilla nutans* var. *bracteata*, &c. Those with doubtful names were referred to Kew.

Diates bicolor (?).—Col. Clarke forwarded a blossom, as it was doubtfully correctly named. Mr. Ridley undertook to report upon it.

Cankered Rose.—Mr. Plowright sent a branch of a Rose, requesting if any insect agency was present. Mr. Maclachlan could detect none, and the cause was apparently not fungoid.

Cæoma Laricis and *Ecidium Pini*.—He also sent specimens of these fungi. The former, Mr. Plowright observes, is new to this country. "It is very abundant at Lynn at the present time, hardly a Larch I have yet examined being free from it; but it is never very abundant in point of quantity." The *Ecidium Pini* he describes as being fairly abundant, and that it is the subsequent condition of *Coleosporium Senecionis*.

Puccinia suaveolens on *Carduus arvensis*.—Mr. Plowright sent specimens of this sweet-smelling fungus.

Rhododendron lanatum.—Several fine trusses of this Himalayan species were sent by Mr. W. Farrant from the Isle of Man. The blossoms were larger than those figured by Hooker. Mr. Mangles observed that he only knew of five large plants in this country, but the flowers sent were excep-

tionally fine. He also sent a truss of the sweet-smelling *R. Fortunei* and some of *R. niveum*.

NARCISSUS ABSCISSUS (N. MUTICUS).

ONE of the latest of all the Daffodils, and for that reason especially valuable, is the variety shown in fig. 91, which, though long an inhabitant of England, is comparatively unknown in many gardens. The engraving was prepared from plants in Mr. T. S. Ware's nursery at Tottenham, where several beds a week since were just becoming attractive when the majority of other Daffodils were either fading or quite out of flower. It is there grown under the name of *N. muticus*, which was bestowed upon the plant by Mr. J. Gay many years since, when it was described in a French botanical work. In most English collections, however, it bears the title of *N. abscissus*, which is a rendering of Parkinson's "clipt trunk" Daffodil, that is reasonably

Fig. 91.—*Narcissus abscissus*.

supposed to be identical with this plant. At the recent Daffodil Conference it was admitted as a botanical variety of *N. Pseudo-Narcissus*, ranking with *cambricus*, *lobularis*, *Telamonius*, and *princeps*. It is, however, so distinct in appearance that some have been tempted to regard it as a species, and such an opinion is excusable, though having regard to the surprising divergencies obtained in this group it cannot be considered as more than a variety.

No special treatment is needed; any ordinary garden soil suits it, and with very moderate care it will grow and flower as freely as could be wished. The blooms are pale yellow, the petals lighter than the crown, which is remarkably long, straight, and tube-like.

ENGLISH GIANT OAKS.—In an article by Mr. W. Senior in Cassell's "Picturesque Europe" on "The Forest Scenery of Great Britain," he states that at Welbeck there is the Greendale Oak, an Oak estimated to be by one authority seven hundred, and by another one thousand five hundred years old. This Oak is probably the Methuselah of his race, although it may be noted that there are new forests which do not, through their local historians, advance plausible claims for a like distinction. The Greendale Oak, nearly one hundred and fifty years ago, was deprived of its heart by the eccentric desire of a former owner to make a tunnel through the trunk

This novel piece of engineering was effected without any apparent injury to the tree; an opening was made through which the Duke of Portland drove a carriage and six horses, and three horsemen could ride abreast. This arch is 10 feet 3 inches high and 6 feet 3 inches wide. A cabinet made from the excavated Oak wood for the Countess of Oxford is one of the curiosities of Welbeck Abbey (the seat of the Duke of Portland). It is ornamented with a representation of the grand old tree, which is now shored and supported against the elements, before which it must ere long succumb. The Spread Oak of Thoresby extends its arms over 180 feet of ground, and can give shelter to one thousand horsemen. In the hollow of Major Oak seven persons have dined with comfort, and that is of course impossible without unrestricted elbow-room. This tree is remarkably perfect in form, the true type of a sturdy Oak that is still prepared to brave the battle and the breeze. The Parliament Oak is a more decrepit patriarch of Sherwood Forest; it is supported by friendly artificial aids, and its trunk is now split in twain—symbol, it might be said, of the Government and Opposition, which are the life of the system whose name it bears.—(*Forestry.*)

CATS IN GARDENS.—Everybody who has a garden knows how attractive and fascinating some plants are for cats—such as Valeriana Phu and Nemophila. Can any of your contributors give me the names of any plants, perennial or annual, to which cats have a repugnance, and which would tend to repel their constant invasion of my flower beds?—G. O. S.

HARDY FRUIT GARDEN.

Summer pruning.—This consists in removing the tender young lateral growths at the third or fourth leaf from the base to form fruiting spurs, and as it is usually done with a thumb and forefinger, it is somewhat incorrectly termed pinching. Let not beginners be misled by the term, for the shoots are not pinched or bruised, but are taken off with a clean nip. Pears, Plums, and Currants are all sufficiently advanced for the first pruning, but only strong healthy trees should be done; all weak or sickly trees should have the growth left entirely unchecked till health and vigour are fully restored. Young unformed trees require stopping both in branch and stem, as well as in the lateral or side shoots, our aim being to waste none of the main growths upon undue and useless extension, but to nip off the tips at every 12 or 14 inches to induce the buds to start into growth to furnish the stem with branches and the branches with spurs, so that when autumn approaches again the only clean unpruned growth will be the last shoots of the year. Let no time be lost, then, with young trees now, if till the middle of August we wish so to guide the growth that a gain of two years may be effected over what would happen if the growth were left unchecked. After that time we prefer to discontinue the nipping, and consider the advice often given to continue it throughout the season of growth as erroneous and mischievous, late nipping inducing much abortive growth, soft and unripened from buds that should remain dormant till the following spring.

Disbudding.—Do not stop all shoots alike. Some will be crowded, and then disbudding must be resorted to, and enough shoots removed to allow the full play of light and air around those which are retained and stopped. Here, again, sound judgment is requisite to enable one to discriminate between trees of robust and vigorous habit requiring extra space for each branch and spur, and those of medium vigour, where the growth may advantageously be left thicker. The fruit of Peaches and Nectarines is now set and swelling freely, disbudding may therefore be done—gradually where the foliage is much blistered, quickly where the shoots are healthy and strong. Retain no useless growth. Nothing can be more unwise than to lay in a number of lateral growths now, most of which must be pruned in winter. Our object is to keep the tree well furnished with fruiting wood over the entire space of wall assigned to it, and to supply new growth from a point as near the base as possible. Assist both fruit and wood growth with frequent waterings of sewage, tie and nail young growth as it gains length, and see that no noxious insects take to the foliage.

Now is the time to apply sewage freely among bush fruit and Strawberries; let this be done with no sparing hand, but take care that enough is given each time to reach all the roots. The master's eye is much required while this work is proceeding, careless or idle workmen often shirking the thorough performance of this and other work. Leaf, fruit, and branch are now in full activity of growth, making demands upon the soil that quickly exhaust its store of nutriment, hence our urgent advice to pour on sewage or liquid manure unsparingly to assist the growth and so promote its full development. Bear in mind how great must be the strain upon a tree or bush in full bearing; in the brief space of four or five months it has to mature a crop of fruit and to make new growth and fruit buds for next season's crop. Whether this be well done or not very much depends upon a full strong flow of sap from the time when root-action begins onwards throughout the season of growth. There

must be no lack of fertility in the soil, no drought, no diseased foliage, no crowded growth, no overcropping, all of these being matters which come fully within the scope of our work, and are mentioned as being preventible by the exercise of due care, skill, and timely forethought.

FRUIT FORCING.

Figs—Early Trees in Pots.—When the first crop is gathered, as will soon be the case from trees started in November, a return will need to be made to the treatment of trees swelling off their crops. Should red spider have appeared, which is not improbable, the leaves must be thoroughly washed on their under surface with an insecticide at a safe strength, and the trees forcibly syringed twice a day. The loose portion of the mulching can be removed, and short partially decayed manure supplied with clear liquid manure. Where the second crop has set thickly, as it will on free-bearing sorts such as Brown Turkey, Negro Largo, &c., which always force well, the embryo fruit must be thinned liberally, as it is important the trees be not too much exhausted by carrying a heavy second crop, or they will not rest early enough or be able to carry a good first early crop another season. Growth after this will necessitate frequent attention to stopping and training, as the best coloured and flavoured fruits are always produced on vigorous shoots fully exposed to sun and light.

Succession Houses.—When the fruit begins swelling a higher temperature and drier atmosphere will hasten the ripening, but care must be taken to afford liberal supplies of tepid liquid manure to the roots, and syringing regularly twice a day, as any sudden check will prove highly injurious to the fruit. As the crop approaches ripening it is not advisable to wet the fruit if it can be avoided, but a good atmospheric moisture can be secured by keeping the mulching, walls, and paths properly damped, and the moisture can be kept from injuring the fruit by maintaining a gentle circulation of air by the employment of gentle fire heat. In a hot and dry house the Fig soon becomes infested with red spider and scale, and the wood stunted, the trees rest because they are exhausted, and the second crop is weak and rusty in appearance; but fed liberally, ventilated freely with heat, and syringed each time they are cleared of the ripe fruit, and they will then keep healthy and able to carry good second crops of fruit—nay, they become perpetual bearers. To keep a Fig in continual bearing it must, of course, be constantly growing, and for this reason the extension system is eligible, as the leading shoots are allowed to extend without stopping until they reach the extremity of the trellis, when they are cut away to make room for others succeeding them.

Figs in Unheated Houses.—These, notwithstanding the recent cold weather, are showing plenty of fruit, and in the event of a fine summer will prove very acceptable in August and September. Figs in all cases should be confined to reasonable limits at the roots, and assuming these are inside the house, with the borders well drained with broken bricks and old mortar rubbish—materials upon which they seem to thrive—the treatment recommended for succession houses will apply to these; only, in cloudy weather the afternoon syringing should be dispensed with, whilst in bright weather it should be performed early, with the sun heat shut in to insure the drying of the foliage before night. In such structures the shoots should be trained a good distance apart, so as to admit light and air freely to the growths, and close stopping should be avoided, as it tends to the production of useless spray and late growths, which do not get properly ripened before the leaves fall. The safe plan is to procure short-jointed wood.

PINES.—Now that the sun has considerable power means should be adopted to fully utilise its best influences, but in doing so proper care must be bestowed on the ventilation, which, when there is the prospect of a fine day, should be attended to early in the morning, because there cannot be too much moisture about Pine plants, but it must be dispelled from the plants before powerful sun operates fully upon them. In order to maintain a good condition of moisture about the plants, moisten all available surfaces about the house freely whenever they become dry, especially at closing time, which should be sufficiently early in the afternoon to keep the temperature at 85° to 90° for some time afterwards. Syringing will be needed almost daily in bright dry weather, and when the plants are growing they should never be allowed to be without water in the axils of the leaves, as many feeding roots exist around the stems of the Pine plants, which can only derive support from the moisture in the axils of the leaves. Be careful not to let any plants become dry at the roots, and when needed give thorough supplies with some guano in the water or other stimulating agent, being careful to apply it in a tepid state, and avoid giving too powerful doses. In very bright weather a slight shade will be useful where the plants are in houses with large panes of glass for two or three hours at mid-day, but the thinner the better; all that is necessary is to prevent the sun from scorching the leaves or fruit. Employ no more fire heat than is absolutely necessary to maintain the requisite temperature for fruiting and other plants, 70° to 75° at night for fruiters, and 80° to 85° by day; other plants 5° to 10° less.

CHERRY HOUSE.—The recent sunless weather has somewhat retarded the fruit, but the most forward are now ripe, and the main crop very nearly so; therefore, with a view to give colour and quality, ventilate a little constantly, and whenever external conditions are favourable ventilate freely. Be careful not to wet the fruit, but maintain a moderate degree of moisture in the house by damping available surfaces occasionally. As the growths elongate and need tying-in do so, allowing plenty of room in the ties for the swelling of the shoots, and stop all growths not required at the fourth or fifth leaf. During cold sunless weather keep a gentle warmth in the pipes so as to allow a circulation of warm dry air, and it will also be needed on cold nights. Keep a sharp look out for aphides.

Strawberries in Pots.—At this season forcing Strawberries is under

the best of circumstances a matter of difficulty, both in keeping the plants clean and in having a proper supply of fruit. Arrangements should consequently be made whereby a succession of fruit can be secured, which can only be effected by plants kept moving to succeed each other in close order, whilst crops that are ripening in advance of the demand may be retarded by keeping them cooler. Much can now be done towards a late supply of forced fruit by bringing on the plants in cold pits, plunging them in ashes near the glass, and with plenty of room to allow of a free circulation of air, and from these plants can always be taken to fill the place of those ripening. Apply liquid manure at every alternate watering, and thin the fruits well as soon as set where extra fine fruits are wanted.

PLANT HOUSES.

Zonal Pelargoniums.—These should now be flowering freely in the conservatory, and will require supplies of weak liquid manure. The smell arising therefrom is often objectionable in such structures, and some reliable artificial manure may be applied in small quantities to the surface. Successional batches of plants must be kept dwarf and sturdy by having them close to the glass and giving abundance of ventilation. Young plants should be potted and stopped as they require it, and the usual number for late autumn and winter flowering should be propagated without delay. These may be inserted singly in small pots, and will soon be rooted if stood in a temperature of 60°. As soon as they are rooted pinch out the points of the plants, and as soon as they have again commenced growth place them into larger pots.

French and Fancy Varieties.—The earliest of these will now be in full bloom, and will be most acceptable in houses that have to be kept gay now the whole of the spring-flowering bulbs are over. Care must be taken that these plants are free from aphides before they come into bloom, for if subject to fumigation afterwards their flowers will fall. Pay every attention to the later plants, keep them near the glass to ensure dwarfness, and tie out the shoots to stakes. Those rooted some time ago should now be potted, and if the points of the plants were pinched out as soon as rooted they must not be pinched again, or they will not bloom satisfactorily.

Petunias.—Supply the plants now coming into flower with short stakes, or their shoots will fall about and look unsightly when in flower. As soon as the flowers are formed feeding should commence. These plants soon draw up weakly if not kept close to the glass and in a structure that is well ventilated, and when in this condition half their beauty is gone, for no plants look worse when badly grown than Petunias. Do not employ any shade, but grow them in the full sun, stopping and tying out the shoots as they need it. Young stock should be potted, and cuttings inserted for later flowering.

Cockscombs and Celosias.—The former, if sown as directed and placed in small pots, will now be showing their combs, and should be placed into 6-inch pots. One or two crocks at the base of the pots will be sufficient, for the plants must be potted as low as possible; for this purpose remove the lower foliage. After potting give slight bottom heat, and keep the plants close to the glass and in a night temperature of about 60°. It is important that they should be kept near the glass, even if they cannot be given bottom heat, or they will draw weakly, and from such plants large fine combs cannot be expected. Celosias sown at the same time will be ready for the same sized pots, but these should not be potted deeper than when in their smaller size. After potting place an upright stake to each, and syringe liberally to keep down red spider. Good loam, a third of leaf mould and manure, with a dash of sand will be found a suitable soil.

Mignonette.—Where the tree forms are grown as standards and pyramids for flowering in pots during the winter seed should now be sown. It is best to sow it in 3-inch pots which have been well drained and filled with a compost consisting of good loam, leaf mould, and sand. Sow a few seeds in the centre of each pot, and after watering them stand them in a temperature of 60°, and cover with glass until the seeds germinate. As soon as they are well up thin out the plants to one, leaving the strongest in the centre of the pots. To grow Mignonette for winter successfully the plants must be gradually hardened by the time they are in 6-inch pots, and must not be checked in any stage, for if their growths become hard or woody they seldom grow freely afterwards.

Roses.—Plants that have flowered must have every care and attention, and must not be placed out of doors, as is too often the case. They should have a light position in a cool house, being liberally syringed and watered until they can be safely hardened. If placed out direct from the forcing house their foliage is injured and destroyed, and instead of the plants increasing in size and strength for another year they will be feeble and only produce poor flowers, if any. Late batches that have still to flower should be well cared for and not be hurried forward, but if possible brought into bloom under greenhouse treatment. Roses dislike a close confined atmosphere at any time, and under such treatment form long slender flowering shoots that have not strength to support their blooms when fully developed. Although air should be given them liberally cold draughts must be avoided, or mildew will soon establish itself upon them. Those to flower just before the border plants should still have the protection of cold frames, but when fine during the day the lights may be thrown off. If these plants are coming forward too rapidly remove those in the most backward condition to a more northern position, which will retard them wonderfully.

THE FLOWER GARDEN AND PLEASURE GROUND.

Sowing Seeds of Perennials.—There are numbers of very serviceable

flowering perennials, the seed of which ought to be sown at once. As a rule we are apt to delay sowing till after the greater part of the propagation of the summer bedding plants is completed, and as a consequence many of the kinds do not have time to become sufficiently strong to flower as they should do.

Campanulas.—There are few more effective plants in the mixed border during the early summer months than *C. Medium calycanthema*, blue, and the white variety, *C. pyramidalis*. White and blue varieties are also remarkably showy, but are not perfectly hardy, and require to be wintered in cold frames. Fill well-drained pans with fine light soil, sow thinly, press the minute seeds into the soil, and very lightly cover with fine sandy soil. Water through a fine rose, cover the pans with a square of glass, place in a handlight or frame, and keep them moist, close, and shaded till the seedlings appear. When the seedlings are large enough to handle prick them off thinly in pans or boxes of fine soil, and when growing freely gradually expose the plants to all weathers. Before they are crowded plant them about 12 inches apart each way on a fairly rich border. In the autumn some of the strongest of the medium varieties may be potted for an early display under glass, the bulk of the two pyramid sorts being also similarly treated, some for flowering in pots, and the remainder returned to the borders in the spring.

Auriculas and Polyanthus.—Last season's seeds of these ought to have been sown early in April, while the seed saved this year may be sown directly it is ripe, at which time it germinates more quickly and surely. Sow in pans of soil as advised in the case of the Campanulas, and as it is rather late place the pans in a slight hotbed. The seed of both often germinates very irregularly, and it may be fully twelve months before all have started, consequently the soil in the pans must not be shaken out, but the seedlings as soon as they are large enough to handle should be pricked-off in pans of good sandy loamy soil and returned to the frames till of good size, when they should be planted out. They delight in a well-worked and fairly rich soil, the position best suited to them being shaded from hot sunshine. The Alpine Auriculas are principally grown in the open, and among these are many very attractive sorts. The Gold-laced Polyanthus is the most generally preferred.

Carnations and Picotees.—Where a large number of cut flowers are required a considerable number of seedling Carnations and Picotees should annually be planted out. These will yield a number of blooms during the season following sowing and planting, but it is the next season when they flower so profusely and to such an extent as to almost exhaust the plant, hence the necessity of annually raising more seedlings. A packet of mixed border varieties will sometimes produce 60 per cent. doubles, while the singles are frequently the brightest in colour and find favour with many. Sow the seeds in pans or boxes of good loamy sandy soil, cover lightly, water through a fine rose, cover with squares of glass, place in a cold frame or very gentle hotbed, and shade from bright sunshine. Directly the seedlings appear remove the glass, gradually harden them, and when they have formed their second leaves prick them off thinly or about 4 inches apart each way in boxes of fine loamy soil, and return to the frames till they are re-established. Finally transplant to a deeply dug bed or border, which will better suit them if it received a liberal dressing of loam from old Cucumber beds. The plants may be arranged about 9 inches apart each way, and must be carefully protected from slugs.

Aquilegias and Delphiniums.—These are usually sown on warm borders, but are with greater certainty raised in cold frames. The seed may be sown in boxes or pans of good soil, and the seedlings eventually be pricked-out on a good border and shaded from bright sunshine for a few days. They may be transplanted to the mixed border either in the autumn or spring. Delphinium formosum is one of the brightest and best, and this if sown early will flower the same season.

Wallflowers and Stocks.—There are no better known or more popular plants than these. This is as it should be, seeing how easily grown as well as hardy and free-flowering they are. Of Wallflowers the best we have grown is Veitch's Dwarf, a compact rich-coloured sort; and Covent Garden Blood Red is also very good. Harbinger is a good brown sort; and for bedding purposes especially the Belvoir Castle Yellow is much liked. The double German Wallflower produces large spikes of bloom, the majority of which are very double. The Stocks to be sown at the present time are the Brompton well-known hardy sorts and the Emperor, the latter not being perfectly hardy. All may be sown on a warm border, or if the soil and position be cold and unfavourable in handlights or cold frames. Draw the drills shallow and about 5 inches apart, covering the seeds with a little sifted light soil. Prick out the seedlings before they are crowded on a good border and about 6 inches apart each way. In this manner strong bushy plants will be obtained, which may either be transplanted to the flower beds in the autumn or be allowed to flower where they are. The Intermediate and East Lothian Stocks frequently stand the winter, especially if the position be well drained. They are extremely serviceable either for autumn or spring flowering. For the former they should be sown late in April on slight hotbeds, and for spring flowering June is quite early to sow.

Sweet Williams.—These are again becoming popular, and where well grown are very showy and useful. The single varieties are preferred, the seed to be sown at once on a warm border or under handlights, and be treated in every respect similarly to the Wallflowers. We prefer to plant in masses, and they thus prove surprisingly attractive.

THE BEE-KEEPER.

HUNGER SWARMS, FERTILE WORKERS, AND BEES TRANSFERRING EGGS.

A VERY common occurrence during the spring months is that of bees and queen leaving the hive. Such swarms are sometimes mistaken for natural ones, and sometimes termed hunger swarms. As far as my experience goes, not in one single instance did I ever see such swarms leave the hive from that cause. I always considered the exodus due to some defect in the hive, such as incipient foul brood, and more particularly when the interior of the hive was in a cold damp state. The bees, being unable to raise the temperature sufficiently, take the opportunity the first fine day and leave the hive, which is generally repeated should the bees be returned without the precaution of thoroughly heating and drying the hive. There is nothing better for this purpose, if the day be fine, than exposing the combs to the influence of the sun, but a few spare hives with dry and sweet combs kept over from the preceding summer will be more suitable.

Do bees transfer eggs from one cell to another? is a question of considerable importance in apiculture. There have been many assertions attempting to confirm that they do so, but not one single case of proof nor anything likely to convince the observant bee-keeper has ever been adduced by the advocates of such a theory. On the other hand, I have made a searching inquiry of the first experimentalists of the day, and not one can make the assertion positive. I have myself devoted much time over a long term of years, sacrificing hives and labour to discover if bees really transferred eggs, but in all my experiments I never observed bees transferring eggs. I am not prepared to say that it cannot be done, because I have transferred larvæ and had the satisfaction to see these nursed and hatched, but I do say emphatically that as yet we have had no proof from a reliable source that bees transfer eggs. The question may, perhaps, be asked, Did I never find eggs in a comb that I knew the deposed queen had not access to? To this I must answer in the affirmative; but in every case there were two queens or fertile workers, which is sufficient to account for the erroneous opinions held by casual observers.

A case of the kind mentioned in my apiary at present will illustrate that phenomenon as well as others. During last autumn, while clumsily manipulating a hive through ill health, I allowed a number of the bees to enter a Carniolian hive whose queen was killed by the stranger bees. Being unable to put it right it stood over the winter until a month since, when I deposed the unfertilised drone-producing queen, supplying the hive with eggs and larvæ from a Cyprian stock. The bees were reluctant to accept the Cyprian worker brood, preferring to raise queen cells over the drone brood, which I destroyed and added another piece of comb containing Cyprian larvæ, which they also rejected, as I found on examination a day or two after, as they seemed to be satisfied with a cell on the first piece of comb given. This cell had the peculiarity of not being a royal cell nor even a drone cell, but simply a worker cell a very little more convex on the seal than ordinary worker cells, and not sealed until at least nine clear days after the deposition of the eggs. Anxious to be accurate, and cognisant of the time of evolution, I examined it daily until it hatched, on the eighteenth clear day, a beautiful average-sized Cyprian queen. Meanwhile an examination of the combs betrayed many newly laid eggs and royal cells containing eggs or grubs in different stages of formation, and this more than a fortnight after the deposition of the queen.

The foregoing is sufficient proof, were such a thing wanting, that fertile workers and queens exist together; and queens raised in worker cells, which is not uncommon, is a cause of much mystery to the ignorant, and apt to cause some bee-keepers to form wrong conclusions. The extreme coldness of the weather has prevented the queen mating yet, but the drones are very lively and seem preparing for a wedding trip whenever the sun shines; and I am in hopes that one of these drones from fertile workers will fertilise the queen, which they are capable of doing, having had queens fertilised by such drones before. If all goes right with the queen I will let your readers know the result. Another thing in regard to the bees of this hive is that they are aged, no bee being hatched in the hive since the end of July, and to carry out the internal economy of the hive will be required for two months to come, which according to precedence will be alive at the end of that time.

The difference of opinions by apiarians on matters such as the above and apiculture in general must be very perplexing to

beginners in bee-keeping, but why should there be so many opinions respecting things so patent to the eye? Where it is opinion and surmise only, difference of opinion and controversy are quite allowable, but to discuss proven facts serves no good purpose further than it may bring subjects before the novice that would otherwise have escaped his attention. Truth and consistency must, however, be the rules that arguments are based upon. If the former is to be established we must, to accomplish that end, be moderate and not go to extremes. A medium path will always in all things accomplish most. Reflect for a moment on the advice, given by some, to save and unite condemned bees. This is very good, but these advisers teach that bees should be fed in autumn to induce young bees being bred as the old ones are extinct or are of no use by spring. Now what is the use of uniting bees in autumn if that were true? but it is not. Bees, if properly managed in autumn and rightly prepared for winter, are greatly benefited by the doubling process in autumn. Your excellent old contributor, "A Renfrewshire Bee-keeper," long since alluded to this, and later on Mr. Pettigrew advocated and ably carried out the same system; in fact it is the system which has been carried out in Scotland from time immemorial, which I may allude to some other time; but let the beginner remember, to be successful with bees he must assist Nature, never thwart it, and the less he performs of the artificial and superficial work the better. Preserve the lives of the bees by quiet throughout the winter and spring, then he will be gratified to see the bees living in summer that he united in autumn.

Before dismissing the subject altogether there is one part of very great importance I desire to mention—viz., the pages of this Journal during the late Mr. T. W. Woodbury's time teem with much good and reliable information; in fact, so much so that I feel satisfied and justified in saying that since the time of the death of that lamented gentleman and able apiarian no advance has been made in the general management of bees. There has indeed been a wider spread of the knowledge of apiculture, but the information has in many cases been taken from these pages, often without acknowledgment.

I shall mention only one subject now—viz., the Italian or Ligurian bee and other foreign varieties. I will not enter into a discussion upon the subject further than saying that the introduction of the Ligurian bee and other varieties has been an inestimable boon to bee-keepers. Both the pure breeds as well as the crosses, particularly the latter, have given the largest harvests of honey ever obtained in this country, and the idea that they do not work upon Heather and do not collect a surplus of honey or that they are liable to foul brood is incorrect. Were it the case, as some are of opinion, that the foregoing is true, the bees would have ceased to exist long ago. It must be with the bee-keeper and not with the bee that the fault rests, because neither the records of the above gentlemen and many others, as well as myself, can corroborate the assertions of these wholesale condemners. In almost every failure with these bees I could trace the fault in the smallness of the hive, or the stock was not far enough advanced to get the advantage of the honey season. These bees will not store honey unless the stock hive is sufficiently large to allow the queen full powers in her egg-laying. It must also be remembered that, though some imagine that one hive is as forward as another, it may not be so. Then in our short and uncertain honey seasons eight days make all the difference between a surplus of honey or not, so that a hive but a week behind may miss the glut when the one in advance obtained it.

Two important matters in the management of these bees I would strongly advise bee-keepers to attend to—viz., that of keeping them in large hives, without which no profit will be had; and secondly, be sure and have them forward in time to catch the honey glut, after which report particulars as to failure or success, so that all may be benefited thereby and come to one opinion not only as to varieties of bees but on the management as well.—A LANARKSHIRE BEE-KEEPER.

FOREIGN BEES.

HOPING this discussion may be of service to bee-keepers I add a few remarks to what has been already written on this subject. My knowledge of the various races is a practical one, and not gathered from reading any journal American or British. I was one of several who, like "Hallamshire," had hoped we had found a treasure in these orientalisks, especially as the Ligurians were deteriorating. We tried to learn their peculiarities, which the bees were not slow to teach us; and the unanimous conclusion we came to was that Cyprians—and we know they were genuine—cannot be handled with smoke any better than Syrians.

But questions of profit and management I regard for the present

as side issues; we are considering that of foul brood. The general opinion is that foul brood may and does often proceed from chilled brood. This I do not deny, but I am more inclined to the idea held by Mr. Cowan and many others, that it is epidemic; and if your hives are in a certain condition they may be affected while your neighbours' may escape, just as epidemics most readily attack unsanitary dwellings. The Ligurians, Cyprians, Syrians, all alike, by their restless marauding disposition get into a dysenteric condition that very speedily develops foul brood; and the great fault I have to find with the Cyprians and Syrians is that they are too fond of visiting their neighbours and so carrying their disease with them. We all of us found within forty-eight hours of our setting these yellow bees in our apiaries that all the other hives in the neighbourhood, some as much as half a mile from us, had a few of them.

The Ligurians once had the character for gentleness, but are now called by some, "demons," and, rightly or wrongly, I lay this to the door of the blood that has been transfused into them from the east for the purpose of improving their colour, and I believe their propensities for developing foul brood has the same origin. I have no interest whatever in praising or condemning any particular race of bees. I was once a hearty champion for these yellow beauties, and was very slow to confess my altered convictions; but I am not alone in this matter, and recently I met the only keeper of foreign bees I know at present in my immediate neighbourhood, and he said he was fast coming round to my way of thinking, as he had lost two stocks of Cyprians this spring in a dysenteric condition, while his Carniolians and blacks were doing well.—J. P. S.

TRADE CATALOGUES RECEIVED.

Auguste Van Geert, Ghent, Belgium.—*Catalogue of New Plants (illustrated).*

P. Van der Veld & Sons, Lisse, near Haarlem, Holland.—*Trade Catalogue of Dutch Bulbs.*

J. Linden, Ghent, Belgium.—*Catalogue of New and Rare Plants (illustrated).*

James Dickson & Sons, Chester.—*Catalogue of Plants for the Flower Garden and Conservatory.*

* * All correspondence should be directed either to "THE EDITOR" or to "THE PUBLISHER." Letters addressed to Dr. Hogg or members of the staff often remain unopened unavoidably. We request that no one will write privately to any of our correspondents, as doing so subjects them to unjustifiable trouble and expense.

Correspondents should not mix up on the same sheet questions relating to Gardening and those on Bee subjects, and should never send more than two or three questions at once. All articles intended for insertion should be written on one side of the paper only. We cannot reply to questions through the post, and we do not undertake to return rejected communications.

Books (J. McK.).—It is doubtful if you would be able to obtain the particular edition of Withering's "British Botany" mentioned except from a second-hand bookseller. There is, however, an edition published by Simpkin, price 10s. 6d. If you require a good introductory work, Notcutt's "Handbook of British Plants," published at this office, price 3s. 6d., post free 3s. 8d., will prove serviceable to you, as the descriptions are clear and concise. (C. P.).—As an elementary work you will find Sir Joseph Hooker's primer on botany (published by Macmillan, price 1s.) very useful. Professor Oliver's "Elementary Botany," published by the same firm, price 4s. 6d., will serve for slightly advanced study.

Garden Sorrel (A. W., Sussex).—Undoubtedly there has been a "great mistake" if seed of the plant you have sent was supplied you for Sorrel. Possibly, however, Sorrel seed was sown but did not grow, and the weeds are the result of seed that was in the soil; however, be that as it may, the plant you have sent is not Sorrel, and the sooner you get rid of others like it the better.

Mushrooms (A Subscriber).—Your letter shall be forwarded to the individual in question, and you may possibly hear from him. We are unable, however, to give you any assurance on that point. You had better send your questions to us in writing; that is the only form in which we are able to give a guarantee that they will be attended to.

Pruning Fruit Trees (Inquirer).—The principles of pruning, as referred to by Mr. Luckhurst, apply to all forms of fruit trees, only in the case of trees on walls it is often requisite to encourage the growths of the lower branches and suppress those above, with the object of furnishing the wall

equally throughout. Your letter, however, shall be sent to the author of the article in question.

Disposing of Books (F. H., Oxon).—We can suggest no other mode for disposing of your books than by advertising them, briefly stating their condition, the published prices, with the prices you desire, and possibly you might find a purchaser.

Climber for the Back Wall of a Greenhouse (C. D.).—It is too much to expect one plant to fill a wall 17 feet long in one season, and your best plan will be to employ several. Heliotrope is quick-growing and useful. Lonicera sempervirens is another free-growing and pretty plant, which flowers throughout the greater part of the year. Some of the taller Zonal Pelargoniums would be suitable, with Cestrum aurantiacum and Sollya heterophylla. Cobaea scandens variegata and Rhodochiton volubile are rapid-growing plants, and both flower abundantly.

London Market Fruit Growers (J. C., Barnsley).—It is very difficult to procure the names and addresses you require, but the following include some of the largest growers both of indoor and outdoor fruits. The names of the districts in which they live could, however, only be obtained, though letters would probably find them:—Messrs. Mann, Wilmot, Norris, Smith, and Warren, of Isleworth; Poupart, of Barnes; Lodge, of Mill Hill; Smith, of Twickenham; and Sweet, of Leytonstone.

Salting Asparagus Beds (W. W. W.).—Salt may be applied at once in sufficient quantity to destroy any weeds that may be growing in the beds, and when further weeds appear apply salt again, and continue the practice throughout the summer. About three dressings usually suffice with us, and we always have good Asparagus and no weeds to exhaust the soil.

Select Single Dahlias (Cambridge).—The following are free-flowering and diversely coloured varieties, very useful for cutting from:—Alba, white; Canary Bird, yellow; coccinea, orange scarlet; gracilis perfecta, scarlet; lutea, yellow; Mauve Queen, lilac; Paragon, maroon; Sunset, crimson yellow, dwarf; Firefly, orange scarlet; Duke of Teck, lilac and yellow; Nora, bright pink; and Painted Lady, shaded rose.

Making Asparagus Bed (G. S.).—It is fully late for planting Asparagus; still we think if you have young plants ready for removal, and they are transferred to the bed quickly and carefully, not allowing the roots to dry in the least, they would, with attention in watering, grow very well. We should cut all the growths that are above an inch through the soil. If you have the roots to purchase and obtain from a distance it is quite another matter, and we cannot advise you to incur the risk of failure in ordering them now. The flower you have sent (No. 1) is Diplacus glutinosus, the other (No. 2) is Piptanthus nepalensis, which you will find figured on page 507 of the Journal, January 22nd, 1882.

Vine Leaves Decaying (W. W.).—The Vine leaves are very thin in texture and comparatively destitute of tissue, which indicates a deficiency of phosphates and potash in the soil, and an excess of nitrogenous matter. Has not the vinery also been kept too close? The evil, however, is mainly at the roots. Possibly these are too deep, and need lifting and placing in fresh soil. If not, and they are plentiful, also near the surface of the border, point in a liberal dressing of wood ashes and crushed bones, or sprinkle on the surface 2 or 3 ozs. of bonemeal and the same quantity of kainit per square yard, watering it in. We think also the Vines need earlier and freer ventilation.

Terminal Blossom Buds (F. J.).—When fruit trees are desired to extend blossom buds should not be permitted to remain at the extremities of the branches. At once remove them, shortening each branch to what appears a promising wood bud, also apply liquid manure to the roots and mulch the soil over them to retain the moisture. The trees have received a check by some cause, and are in a stunted and stubborn state. There is only one way out of it, and that is imparting vigour by generous culture. Such trees should not be allowed to bear, but everything should be done to induce wood growth. To provide leaders we have often had to cut a foot or more from the ends of the branches to where a healthy growth was seen to be starting.

Bouquet Dahlias (Idem).—The plants may either be secured to stakes or pegged down, the former being preferable for promoting quick growth and an abundance of flowers as early in the season as possible. The plants may be inserted 2 feet apart and secured to stout sticks at once, or they may be broken by the wind. They need rich soil and liberal applications of water, with mulchings of manure in dry weather. You will find some varieties grow taller than others, and by noting the respective heights this year you will be able to arrange the plants more effectively in the future. If you prefer to peg the growths down the plants should be inserted slantingly, or you will experience some difficulty in affixing them to the ground.

Plums Failing (Delta).—We can only account for the failure on the assumption that the weather was inclement when the trees were in flower, or at the equally critical period just after the fruit had set. The blossom is not more tender than that of Peaches, but these trees have the shelter of walls, which we presume your Plums trees have not. Plums expand their flowers earlier than the majority of Pears do, and on that account are sometimes placed at a disadvantage. You are by no means singular in having no Plums this year; we unfortunately know of hundreds of trees both of Plums, Pears, and Cherries that will be absolutely barren, although a short time ago they were densely clothed with blossom, which, however, succumbed to the bitterly cold winds and severe frosts that occurred in April. Perhaps your garden is somewhat low and damp, in which case the blossom of fruit trees is always more liable to injury than in higher and drier positions.

Planting Marechal Niel Rose (W. S.).—As we do not know anything about the arrangements of the house, nor the convenience for making a suitable border inside, we are scarcely in a position to determine the best position for planting; but this we know, that with an outside border covered with a frame 2½ feet wide we could grow the Rose satisfactorily. We should prefer stout plants on their own roots established in pots. These may be planted now or at any convenient time when the roots have fairly filled the pots and need more space for extension. Good soil,

tolerably strong, yet porous, careful watering and mulching the surface with manure, with judicious ventilation and scrupulous cleanliness of the foliage—neither insects nor mildew being permissible—are the chief factors in the successful cultivation of this grand Rose.

Eucharis amazonica (J. C.).—We believe that it has been authoritatively determined that there are not two varieties of this plant. What is regarded as the inferior form is simply degeneration arising from defective cultivation. This is not by any means the fault of the cultivators exclusively, but in numerous instances is the direct result of inadequate means for growing the plants well. It is impossible for us to indicate the cause of the failure of your plants without knowing somewhat of the treatment to which they have been subjected. Possibly they have been overpotted, and have not at all times had sufficient heat. Good turfy loam, with an admixture of crushed charcoal or wood ashes, well-drained pots, and a stove temperature, moist in the growing season, and the plants shaded from the sun, are the chief essentials in successful culture. Bottom heat is of great advantage in starting the plants after repotting, and they invariably succeed the best when the pots are filled with roots. Try the plants in fresh soil and smaller pots.

Insects on Rose (Wanderer).—The reddish-brown insect adhering to the stem is the large brown scale. This is objectionable enough and injurious to the plants, but is not the cause of the mutilated foliage. There are at least two enemies attacking your Roses, one of which may be a snail or weevil which eats the leaves, the other the scale that extracts the plant's juices through the stems. The scale may be destroyed by dissolving 2 ozs. of soft-soap in a gallon of hot water, than adding half a wineglassful of petroleum, and applying when cool enough to the stems with a brush. The plants may also be laid on their sides and syringed with the same mixture, provided it is done in a shaded place and the Roses are kept out of the sun for a day or two afterwards. You had better also search with the aid of a lantern for nocturnal depredators. We suspect your plants are in an enfeebled state by defective root-action, inferior soil, or some error in treatment, but on this matter we cannot speak conclusively on the evidence of a "specimen" nearly 2 inches long.

Seedling Alpine Auriculas (Idem).—If the trusses you have sent have been gathered from plants, four dozen of which are growing in a box 18 inches square, in which the seed was sown last March, you have great reason to be satisfied. If such trusses can be produced by plants so crowded, what may you not expect when they are strong and established in good soil with ample room for development? At once divide and transplant the crowded seedlings in good compost in a shaded place, a frame or under hand-lights on the north side of a wall would be suitable; or they may be potted and eventually transplanted where required to flower, either in a border or on rockwork where there is sufficient fertile soil for promoting and sustaining vigorous growth. We note they are border Alpines of the strain of the late Mr. Alexander Honeyman, and are better than we should have expected could be produced in the time and under the circumstances indicated.

Seedling Auricula (J. P.).—The name you suggest has not been appropriated, and you are quite justified in attaching it to your seedling. It is a white-edged flower, of which there are comparatively few of superior merit. Nor can we place this in the first class. Its pale tube is a defect, and the paste is somewhat angular yet very dense. The body colour, purplish black, also appears to run too much into the narrow edge; but by packing in dry cotton wool the meal was smeared over the colour to such an extent that the appearance of the flower was greatly marred. Grow the plant well, and send us flowers next year so packed that they arrive in the same condition as when they were cut. Though not perfect, it is yet the best seedling Auricula that has been sent to us this year.

Soil for Chrysanthemums (Z. Y. X.).—The basis of the compost should consist of rather strong turfy loam, with decayed manure added to the extent of one-sixth, a little less or more according to the quality of the loam. An admixture of wood ashes with a sprinkling of soot and bonemeal, say a 6-inch potful of each to a bushel of soil, would improve the compost. Charred soil is of great value, and you cannot err by subjecting at least a portion of the loam to the action of fire. With a well-prepared compost of the nature indicated you will not require to use sulphate of ammonia or artificial manure of any kind for some time. The mixture recommended on page 285 would be admirable for Chrysanthemums if applied at the right time—that is, when the plants need more support than the soil affords them. It is easy to err by over-manuring during their early stages of growth. We have seen plants ruined by too generous culture during May, June, and July. They grew most luxuriantly, but produced inferior blooms; but, on the other hand, many plants are injured by starvation. You must exercise your judgment in this matter, and we think you will succeed in your object. We are glad the Vines have improved. Early morning ventilation should be particularly attended to.

Nectarine Leaves Skeletonised (W. M.).—The injury to the foliage is neither caused by insects nor fungus, but is the result of defective root-action or a deficiency of food for maintaining the trees in a healthy state. Of this we have no doubt whatever, and if you lift the roots and place them in fresh loam with a mixture of calcareous matter, and at the same time accord the trees otherwise good management, they will produce very different foliage, stouter and greener, that will resist the effects of the sun. The transparent patches in the leaves show a deficiency of chlorophyll. There is, indeed, little or no substance there, and those weak parts shrivel and drop out. We have only once before seen a similar case, and the trees were completely restored by the means above indicated. If there is no fruit on the trees you may lift them at once, and keep the foliage fresh by syringing and shading until new roots form and take possession of the fresh soil; or the lifting may be done immediately the crop is gathered. If it must be postponed, the best thing you can do in the meantime is to apply liquid manure copiously to the roots, ventilate early in the morning, and in very hot weather shade the foliage slightly either by spreading netting on the glass or sprinkling it with limewash applied with a syringe. The trees have probably been overcropped. They are certainly in an enfeebled state, and urgently need renovation. An abundance of fresh roots working freely in good soil will have a magical effect, and if you can carry out our suggestions this summer you will probably have healthy trees next year.

Liquid Manure in Vinery (A Lady).—Liquid manure placed in the evaporating troughs in vineries is either injurious or beneficial according to the judgment that is exercised in its use. Strong guano water and highly heated pipes when the foliage is still tender and the Grapes quite small, and the ventilators left closed too long in the morning, would be very likely to result in the scorching of the foliage and the rusting of the fruit. Your safe course will be to wait until the Grapes commence swelling after stoning before using liquid manure, and then to leave the top ventilators slightly open at night, increasing the ventilation immediately the temperature commences rising in the morning. Then you may expect the ammonia in the atmosphere to prove beneficial.

Pelargoniums and Fuchsias for Autumn Flowering (Idem).—It is quite easy to have the plants flowering in October if you wish them by growing well any free-flowering varieties. Probably those you have will answer very well, and possibly if we printed a list we should simply name several varieties that you possess, and, besides, you give no indication of the number required, and we do not know whether you desire to grow six or six dozen. Grow the Fuchsias in frames in a shaded position in summer, removing the lights on favourable occasions from June to September, and especially at night for the benefit of the night dew; indeed, the plants will only require protection from sun and heavy rains. Some of the finest we have seen were grown outdoors during July and August, the pots partially plunged in ashes on the north side of a wall. The plants must be kept growing freely, repotting them as may be needed to ensure this, and watering and syringing them regularly. If the wood is allowed to get hard you cannot well retard them. Pinch the shoots as they extend 4 or 5 inches, and permit no flowers to expand till September. The plants must never be root-bound until they are placed in the pots in which they are intended to flower, or the wood will ripen prematurely. When the plants are near flowering clear liquid manure, such as soot water, will be very beneficial. The young plants to which you allude are quite amenable to the treatment indicated, and old plants that flower in July, if pruned slightly, repotted, and grown in the same manner, will flower again in the autumn. Zonal Pelargoniums grown practically in the same way, only in a sunny position, will flower equally well late in the season, young plants producing the finest trusses, old ones affording them the most freely but smaller. Plants that have flowered in June, then cut down, and a fortnight afterwards shaken out and repotted, will flower freely in the autumn. Young plants may be topped occasionally till the middle of August, and then have the flower buds picked off if earlier than you wish them. They must not be starved at any time, but be kept supplied with water as needed to promote healthy growth, giving weak liquid manure occasionally when the pots are crowded with roots and flowers are forming freely.

Names of Plants (Pantonian).—1, *Ornithogalum nutans*; 2, *Scilla campanulata*; 3, *Iris foetidissima variegata*; 4, *Pulmonaria angustifolia*. (J. H. E. C.).—*Grevillea Preissi*.—(East Fairleigh).—*Celogyne flaccida*. (G. A. M.).—The large flower is a good variety of *Cattleya Mossiae*. The small, white, fragrant flower is *Rhynchospermum jasminoides*, and the specimen with shining green leaves and white flowers is *Begonia semperflorens*. (E. M. C., Limerick).—Your plant is apparently a *Bignonia*, but we cannot determine the species without flowers. A large number of the plants of this genus fail to flower under cultivation in this country, though represented by strong, healthy, large plants. (M. H. R.).—1, Unrecognisable; 2, A variety of hose-in-hose *Polyanthus*. (Jane).—*Cerasus Padus*.

COVENT GARDEN MARKET.—MAY 14TH.

LARGE supplies of all classes of goods still arrive, prices remaining below their proper standard.

THE SHROPSHIRE BREED OF SHEEP.

(Continued from page 376.)

We will now refer to this class of sheep as exhibited at the Battersea Show in 1862. This useful and rent-paying stock,

which is much sought after in Ireland, was for the third time shown in a distinct class, and quite kept up their character for symmetry, early maturity, great weight, lean mutton, and wool, which it had gained at the previous meetings at Leeds and Canterbury. However, in reverting to the former exhibitions we could find no animal at this exhibition equal to the aged ram two years three months and three weeks which took the first prize at the Warwick meeting, that being the best sheep of any breed or type we had ever seen, and we were informed belonged to Mrs. Baker, nor have we ever since a sheep of any breed or race to equal it in all points. It was, however, not of the South Down cross, nor could we ascertain the mixed races which it represented in so many important respects. Still we found this breed exhibited in grand form at Battersea by taking the best animals into consideration, but they varied very much both in character and quality, which made the task of adjudication a difficult one. We took size and early maturity as the first consideration; but taking these sheep on the whole we did not think them up to the average of some former years, and there was certainly not a perfect animal in Class 1 amongst the sixty shearling rams exhibited. In Class 2 there were only twenty-four animals in competition, but their high character quite compensated for the short number shown. The three prize sheep were wonderfully fine animals; and this only accords with our previous observation of the best-bred stock of the Shropshire tribes, for in all the meetings we have attended where the aged rams were shown in competition with other short-woolled sheep, which was the case previous to the meeting of the Royal Society at Warwick, they were superior in their weight for age and general points to the other breeds in competition as aged sheep, but they could not reach the valuable character of the Hampshire Downs as shearlings.

It is not very important whether this breed of sheep is an original one, for it is certainly an established one, and the type, style, and character can be perpetuated. This breed has risen into note steadily but surely, which is strong evidence of the general estimation in which they are held by graziers in the midland counties particularly, as well as in Ireland, and also in foreign countries to which large exportations have been made for several years past and purchased at large prices.

We will now describe the character of the breed, and it may be remembered that since the extraordinary exertions of the late Lord Chesham of Latimer to improve the Down character of the sheep, many of which as prizetakers have partaken so much of the South Down character in many respects as to induce the uninitiated observer to think that they were pure-bred South Downs. They combine the symmetry and quality of the South Down with the weight of the Cotswold; they possess the fattening tendency of the Leicester without their delicacy of constitution. Their tendency to fatten is connected with such a development of flesh and lean, that a remarkably marbled or mixed fat and lean meat is produced, which may be presented on any table in the kingdom, and especially at the banquets of the wealthy classes of society, where the excessive fatness of the Leicester sheep is particularly objectionable. The price of this mutton ranks with that of the South Down in the market, and when this is a fact, with sheep ranging from 35 lbs. to 40 lbs. per quarter, at the same time carrying fleeces of excellent quality, and weighing from 6 lbs. to 10 lbs. per fleece, it must be considered that such a breed is of great importance and value to the graziers and flock-masters. Crossing has been attempted in various ways, but with any long-woolled breed in admixture the quality of the mutton has deteriorated with a loss of hardihood and constitution of the progeny, and this cross also is not able to withstand the inclement weather of the highlands of the western counties and districts. For these reasons the Leicester cross is objected to.

Our observation of the style and character of the Shropshire sheep induces us to believe that the point of early maturity or weight of the sucking lambs, or those from six to nine months old, may not only be increased, but the quality also by a cross between the Hampshire Down ram and the Shropshire ewe; for it is well known that in the shearling ram classes, when the two breeds were exhibited in the same class at the Salisbury and Chester meetings of the Royal Agricultural Society of England in 1857-58, that the Hampshires were superior to the Shropshires, but in the aged class there were instances in which the latter beat the Hants Downs. Quite independent of this question of early maturity there is another of vast importance, for in mating the Shropshire ewe with the Hampshire Down ram we should expect the increase of the number of lambs would be great. We could not put the number of lambs obtained from the Hampshire Downs at more than a lamb to each ewe, whereas the Shropshires cannot be put at less than 125 lambs to the 100 of ewes. We

shall, however, farther on give information relative to the increase of certain flocks, and which will prove our case in regard to the great increase of lambs to be reared from the cross-breed we have referred to.

In some cases a cross with the Cotswold has been tried, but it has not been received with more favour than with the Leicester, nor is there any reason to expect any increase of the number of lambs through the Cotswold cross than is obtained now by the Shropshire stock as now established. Scarcely any increase of weight has been gained by a Cotswold cross, but the quality of the Shropshire Down mutton has deteriorated in consequence. With ordinarily liberal feeding the Shropshire hoggets will weigh 20 lbs. per quarter at twelve months old, and at twenty months old will frequently average 35 lbs. per quarter through the flock. There is, therefore, no important advantage to be obtained by the increase of weight; in point of fact, if there had been, some strong reasons must have been shown to induce the breeders to sacrifice the point of quality, which is so prominent a feature in the jealous care which has brought the Shropshires up to their present position.

Young men commencing business as flock-masters should give their attention to certain facts which hold good throughout the great majority of breeds of sheep even in their improved character, for we may with little trouble trace it in the wild and original classes of mountain or forest breeds. For this reason, as a rule, we cannot obtain first-class mutton from long-woolled breeds of sheep, taking the meaning of quality as being a fair admixture of fat and lean meat in animals fed for the butcher. Although some animals will prove heavier at weight for age, yet if they are of a long-fleeced variety they are sure to yield an undue proportion of fat compared with the lean, at the same time it is not so well mixed and marbled. In support of this argument the Shropshires which Lord Chesham has exhibited in the improved form, both in shape and wool, as well as general character, have been so nearly of the same style and type as to be almost a counterpart of the pure South Downs; at any rate we have seen them in show pens, especially the ewes, when to a novice in these matters there was little to distinguish them, except that the Shropshires were larger and heavier, and the wool a little coarser and longer in the staple than that of the pure-bred South Downs. These observations we can recommend to the careful attention of breeders of some other short-woolled varieties. The attempt to obtain the greatest weight for age of their stock in some respects is regarded as an improvement of certain breeds, and we regret to say that judges of the present day are frequently apt to consider if form, &c., are equal on the day of exhibition, that those which will yield the greatest weight for age deserve, irrespective of quality, to be rewarded by the judges' approval, without reference to the original character of the breed. Let us name the Hampshire or west county Downs, which on their first being allowed a separate class at the Royal and other exhibitions, those most approved, although being of large size and great weights, were possessed of a style and wool nearly approaching that of the pure South Down. But within the past seven years especially, even those exhibited under the same denomination as Hampshire Downs, sheep having a deeper and coarser wool, have been placed before the highest bred and those yielding the best quality of mutton; in fact, the question has been decided by weight for age.

It is in this way that the character of the improved Hampshire Down, reared and selected with so much care for more than twenty years by the late Mr. Humphrys of Oak Ash, Chaddleworth, Berks, and afterwards maintained by Mr. James Rawlence of Wilton, Wilts, and others, with much strictness and care, have actually disappeared altogether in their pure and original form. Still some exist in various flocks, which are jealously guarded in the interest of their breeders, and may one day come to the front again in the hands of some intelligent and far-seeing flock-master, while those who are breeding their sheep with coarser wool and still exhibiting them as Hampshire Downs will not be able to control the movement brought about by the idea of weight for age, or in the pursuit of weight for age chiefly, will be found no better than deserving only to be merged and mixed with the Oxford Downs. One more observation upon this point we must make is that as it is said, and truly, that nothing ever stands still, but that it must either improve or recede, so it is with breeds of sheep; for it is almost impossible to retain the merit of quality in any breed of sheep if we attempt to improve them in their weight for age by growing longer and coarser wool. We have minutely stated these ideas, because they are as applicable to the Shropshire Downs of Lord Chesham's style and type as they have been in connection with the Hampshire Downs as bred by Mr. Humphrys.

We must now refer to the Shropshire sheep as they advanced

in public favour, and give quotations from the report on the exhibition of live stock at Wolverhampton by the Royal Agricultural Society of England in 1871, furnished by Mr. Jacob Wilson, the senior steward. He states, "In the very centre of their home district, and with so tempting a prize list as that conjointly arranged by the Council and the Local Committee, the Shropshire sheep came out in strong force—to the unprecedented number of 528 animals, though this was to a considerable extent composed of the numerous entries of ewes and lambs. This breed of sheep is rapidly extending its usefulness throughout the country, for to my mind there is no 'better rent-paying' sheep in existence, and I rejoiced to see them forming the chief and prominent feature in the Wolverhampton show-yard." The Judges' report states that "the all-aged rams were the most noticeable feature. In this class we found a large proportion of the animals of marked superiority, Mr. Evans of Shrewsbury and Mr. Mansell of Baschurch, Salop, both taking prizes in this class." In the class for shearling ewes we find Mrs. Beach of Brewood, Stafford, taking the first prize and beating Lord Chesham of Latimer, Bucks; in fact, Mrs. Beach, to have obtained prizes in the other classes for young stock against such a competitor as his lordship, has obtained a very high position, and there can be no stronger proof of the practicability of attaining the uniformity in Shropshire sheep that breeders have so repeatedly been urged to strive for than is shown by the animals exhibited by this lady. These important reports exhibit, in the most satisfactory manner the advance made by this breed of sheep up to the date of the Wolverhampton meeting in the year 1871.

(To be continued.)

WORK ON THE HOME FARM.

Horse Labour.—Horses are now fully engaged in preparing for sowing seeds for the Mangold, Carrot, and Swede crops, as the Potatoes are all planted. We have now been laying out and spreading farmyard manure on the fallows, and have ploughed and drilled the Orange Globe Mangold seed, and at this time we are looking forward for ploughing-in green crops, which is a great object with some farmers where valuable crops of cereal and pulse crops are grown. These are the most important and rent-paying products, together with the sale of hay and straw, the value of the latter to be expended in the purchase of manures, as fodder and litter will not be in so much request where no sheep are kept, but only growing young short-horned steers. All the Mangolds and Swedes will be stored away and cleared off the land in good time for the ploughing and sowing of Wheat in the month of October, still they are looking for a green crop to plough-in, besides the Mangolds and Swede greens, and therefore they should drill these crops at 30 inches between the lines on the flat. This will leave good space between the lines for interculture and preparing the land to receive the Turnip seed, which may be sown broadcast just before the second horse and hand-hoeing of the Mangolds, and when sown broadcast they will when growing not interfere with the Mangold, and at this distance the young Turnip plants also will get sun and air sufficient to give a fair growth of foliage, which is all that is required. Farmers should sow a sort which throws the most foliage for the purpose of ploughing-in, such as the Greystone and other luxuriant-growing varieties. Carrots may now be sown with the best chance of obtaining a plant, and they will be more free from the growth of weeds than when sown after a fallow if drilled at once, ploughing after Rye, Trifolium, or other green-fodder crops, especially if the short Red Intermediate sort is grown. The cost of the economy connected with this system is that it is so much less labour to lift them than the white Belgian or long Red Carrots; in many cases it is of so much consequential expense that many farmers object to growing Carrots of the long varieties. There is great economy in late sowing and of growing only the short varieties like James's Intermediate, for in certain districts they sell well in the vegetable markets, and also they are valuable as winter food for horses in any work in the towns as well as country. It is not too soon now, especially in the northern districts and Scotland, to sow Swedes; and when required for pulling and storing for cattle, instead of feeding on the land, they may be sown now with advantage in any district, and also they may be drilled at 30 inches, Turnip seed being sown and grown in the intervals with the same advantage and for the same purpose as above described in the culture of Mangolds. Where the seeds of Clover have not yet been sown on the Lent corn the sooner it is done the better.
